Charles Darwin

Michael Ruse

Department of Philosophy, College of Arts and Sciences, Florida State University, Tallahassee, FL, USA

Introduction

Charles Darwin (1809–1882) is rightfully known as the father of evolutionary theory. In his *Origin of Species*, published in 1859, he argued not only for the fact of evolution – the natural development of organisms from forms far simpler – but proposed a theory of change. Starting with the ongoing struggle for existence, he argued that some will be winners – they will be naturally selected – and this will lead not only to new kinds of organisms but to adaptation, the design-like features that hitherto had been ascribed to the direct intervention of an all-powerful god. This entry considers all aspects of Darwin's life and work, the predecessors, the influences, and the consequences, both in science and in culture more generally.

The Man and His Life

Charles Robert Darwin was born on February 12, 1809. He was the fourth child (of five) and the second son (of two) of Dr. Robert Darwin, a physician in the town of Shrewsbury, in the British Midlands close to Wales. His paternal grandfather was Dr. Erasmus Darwin, a well-known physician and inventor. His maternal grandfather was Josiah Wedgwood, the founder of the famous pottery works. Because his father was not only successful in his profession but also a very good financier, and because his mother received a very large dowry from her father, young Charles never had to work during his lifetime for his living (Browne 1995, 2002).

One thing we can infer immediately. Although Charles Darwin was a great revolutionary – in fact, one can truly say there are few human beings

who have had quite the effect on our culture that he has had – you should never expect to find him a rebel (Richards and Ruse 2016). He came from a very comfortable, moneyed segment of British society, at a time when Great Britain was the most powerful nation on Earth. He fell very comfortably into the role expected of him, that is to say a respectable, upper-middle-class Englishman. What this means, therefore, is that to understand Charles Darwin and his great achievements, we should never expect to start from scratch. Rather, we should expect to find that he takes the elements of the society around him, draws them into himself and rearranges, and then as it were puts them back on the cultural market. Darwin is going to be a bit like a kaleidoscope. Pieces come from all over, are broken down, and put together again, and we have a whole new picture. Always, when trying to understand Darwin, we should look for the influences around him. There is nothing new in Darwin's work. And yet the work itself was entirely new!

Before Evolution

Charles's father Robert was naturally concerned that his young son would become an idle wastrel. Therefore, when the lad was still in his teens, Robert pushed Charles toward the profession of medicine. However, after 2 years of study in the Scottish capital of Edinburgh, Charles Darwin realized that he simply did not want to become a doctor. Looking for an alternative, and somewhat in despair, Robert next directed Charles in the direction of the church. In order to become a clergyman (of the Church of England), one had to have a degree from a British university. In 1829, therefore, we find Charles Darwin enrolling at Christ's College, Cambridge.

He spent three happy years as an undergraduate. His formal courses were not onerous, and he had much time to pursue the study of biology, an interest that was growing strongly. However, Charles Darwin's first excursions as a full-time scientist came in the area of geology (Herbert 2005). In 1831, he had the offer to go as the captain's companion on board the British warship HMS *Beagle*. The ship, under the command of Captain Robert FitzRoy, was going down to the

Southern Hemisphere in order to map the coastline of South America. FitzRoy was looking for a gentleman who could pay for his own mess bills (that is to say, his food and drink) and who would be somebody outside the line of command with whom he could relax in his spare time. Charles Darwin fit the bill exactly.

Overall, the *Beagle* voyage lasted some 5 years. It went first across to the east coast of South America, starting with Brazil, and then worked its way down to the very bottom to the snowy lands of Tierra del Fuego. It then sailed up the west coast, past Chile eventually swinging out into the Pacific. It made a visit to the group of islands known as the Galapagos Archipelago, now belonging to Ecuador. After that the *Beagle* went southwest to New Zealand and in Australia. It then visited South Africa, made a quick trip back to South America, and finally returned to England in the autumn of 1836.

Charles Darwin very rapidly matured from the role of captain's friend to that of ship's naturalist. He made massive collections of rocks and fossils and animal and bird skins and plants. These were sent back to England for cataloguing and classification. At the same time, Darwin did a fair amount of geology in its own right, as well as studying in some great detail the flora and fauna of the lands that he visited. He proved to be a bad sailor, often being dreadfully seasick. However, most of the time during the *Beagle* voyage, Darwin was not on board the ship. He would get put off at a port and stay there or travel on land and then rejoin the ship at a later point (when it returned having done detailed surveying up and down the coast). Darwin kept detailed diaries, and shortly after the voyage was over, he worked these up into what was to prove a very popular travel book, what became known as *The Voyage of the Beagle* (Darwin 1845).

The greatest influence that Darwin had on the *Beagle* voyage was the newly published work on geology by the Scottish lawyer-turned-geologist, Charles Lyell (1830–1833). Darwin took with him the first volume of Lyell's *Principles of Geology*, and the other two subsequent volumes were sent out to him from England. Lyell was arguing for what came to be known as a “uniformitarian”

view of geology. Lyell claimed that, given enough time, all the varied geological effects that one finds in the world – mountains, valleys, oceans, rivers, volcanoes, and much more – can be produced by regular forces, of an intensity no more than those presently in action. In other words, snow, rain, deposition, silting, volcanic eruptions, earthquakes, and all the other natural effects can produce everything. Darwin was very impressed by this view of the Earth's history, one which incidentally requires a great deal of time. Although his mentors at Cambridge, particularly the geologist Adam Sedgwick (1831), had endorsed a view which came to be known as “catastrophism,” where one supposes massive upheavals every now and then in the Earth's history, Darwin rejected this entirely in favor of Lyell's alternative position.

In fact, the first piece of scientific work that Darwin did, for which he is still rightfully famous, was right out on the Lyellian system. Lyell argued that the Earth is a little bit like a waterbed (Rudwick 1969). That is to say, as one part subsides (perhaps because of deposition of silt from rivers), another part rises. The major puzzle, unsolved by Lyell in the *Principles*, was that of coral reefs. Why do we find these circular, island-like phenomena in tropical seas, with coral growing around their rim? Lyle had argued that these are the relics of now extinct volcanoes. Darwin reasoned that it was highly unlikely that the volcanoes would have come up to, and no further than, the ocean's surface. Rather argued Darwin, the coral had first grown around the edges of islands and then kept growing upward as the islands subsided. He showed this would lead to coral reefs (Darwin 1842).

The uniformitarianism of Lyell had two major effects on Darwin, one scientific and the other religious. On the scientific side, Lyell's insistence that everything be explained by regular laws of an intensity now in operation started to push Darwin toward an evolutionary perspective on organisms, meaning here the belief that organisms are naturally produced by regular laws from other forms perhaps far more simple, rather than by miracles (Ruse 2008). Lyell himself denied evolution, but it was certainly open for a young follower to start

thinking otherwise. On the religious side, Lyell started Darwin on the long path that led eventually toward the end of his life to skepticism or agnosticism. As a young man intending to join the clergy, Darwin had been a practicing and believing Christian – a member of England’s established Protestant church, the Anglican Communion. On the *Beagle* voyage, under Lyell’s influence, increasingly Darwin found himself unable to accept miracles. Therefore, this meant that the Bible stories could not be literally true. Darwin came to reject the idea that Jesus is the Son of God.

It is important to emphasize that Darwin did not now become an atheist – he never became an atheist – but he did start to move from Christian “theism” to what is known as “deism.” By this latter term is meant the belief in a God who is an unmoved mover that is one who works entirely through unbroken law. This deism stayed with Darwin right through his mature life and only toward the end did it start to fade into a form of non-belief. It goes without saying that the truth of evolution is, if anything, proof of the power of God rather than despite it. Everything, including organism life, is produced by unbroken law, without the need of intervention by the deity.

From Evolution to Natural Selection

Darwin did not become an evolutionist on the *Beagle* voyage. However, the visit to the Galapagos Archipelago in 1835 was probably the most important event in his whole intellectual life (Larson 2002). It was there that Darwin saw the giant tortoises of the archipelago as well as the teeming birdlife. To his great surprise, Darwin discovered that the reptiles and the birds differ from island to island. Moreover, although they are like the wildlife of the South American mainland, they are slightly different. Darwin was extremely puzzled how this could be. Yet, it was not until he returned to England and asked a leading authority to examine and classify his birds that Darwin made the move over to evolution. When Darwin was told that the birds from the different islands on the Galapagos are undoubtedly different species, he could see no way of explaining this fact except through a long

process of what he was to call “descent with modification.”

Early in the spring of 1837, Charles Darwin became evolutionist. It is worth noting that probably due to the Galapagos influence, Darwin always thought of evolution as a branching process, starting with an original form that then diverges as the descendants get separated and go their different ways. For this reason, a branching “tree of life” was the picture of organic history adopted by Darwin and from which he never deviated. He may have made a great discovery. Letting it go public was another matter. By this time Darwin was starting to make a name for himself as a very promising young scientist. His work on coral reefs was gaining him much respect. Darwin realized that to announce the fact that he was an evolutionist would be fatal to his professional success. Hence, although he opened some private notebooks and set out on a detailed course of inquiry, he kept his newfound beliefs very much to himself.

As a graduate of the University of Cambridge, that is, as a graduate of the University which had some 200 years before housed the great Isaac Newton, Darwin realized that it was not enough simply to become an evolutionist. As Newton had found the cause of the Copernican system – his force of gravitational attraction that exists between all bodies – Darwin likewise realized he had to find a cause for evolution (Ruse 1979a). It took him 18 months to hit on the solution. Very quickly, Darwin realized that the key to change lies in selection. Animal and plant breeders who want to produce better quality products, fatter pigs, beefier cattle, and fleshier vegetables had realized that the secret to success is picking those which, for whatever reasons, have desired characteristics. Breed from and only from these, very quickly one can effect significant change.

Darwin searched therefore for a natural equivalent to the breeders’ selection. The crucial move came at the end of September 1838 when he read a work by an Anglican clergyman, the Rev. Thomas Robert Malthus (1826). Malthus was interested in the problem of why human beings bother to work at all. Why do we not spend all our days playing and idling away the hours? Malthus’ answer was

that God has made our reproductive inclinations so strong that there is constant population pressure on the limited availability of space and food. This leads to an inevitable “struggle for existence.” Humans therefore must work, and work hard, in order to succeed. Otherwise, they will starve and die.

Darwin took this Malthusian idea and applied it to the world of animals and plants. He argued that for all organisms there is a constant outstripping of food and space supplies, by ever-increasing population numbers. Throughout nature, therefore, there is an ongoing struggle for existence or more precisely struggle for reproduction. Since new variations are always appearing, for whatever reason Darwin never knew, this means that in the struggle some will succeed and some will fail. Those that succeed will on average tend to be different from those that fail. It was Darwin’s great insight to see in addition that the differences are the things that matter. It is precisely because organisms have different features that some succeed and others do not. There will therefore be an equivalent to the breeders’ method of choosing, an equivalent that Darwin famously labeled “natural selection.”

In the course of time, natural selection will lead to change, that is, evolution. It is most important to recognize that for Darwin it was never merely change. It was always change of a particular kind. In particular, Darwin thought that natural selection leads to “adaptation.” By this is meant that the features of organisms are design-like: the hand, the eye, the genitalia, the leaf, the bark, the hunting tactics of the predator, and the evasive strategies of the prey. Why was Darwin so convinced of the importance of adaptation? This was a result of the training he received at Cambridge. Part of the curriculum was the work of the Anglican clergyman William Paley. Paley was the author of the celebrated work *Natural Theology* (1802), in which he gave the definitive exposition of the argument from design of God. The eye is like a telescope. Telescopes have telescope makers. Therefore the eye must have an eye maker, the Great Optician in the Sky.

Darwin accepted completely Paley’s premise, namely, that the world is “as if” designed. Indeed,

in these early years, he did think that the organic world was designed. But whereas Paley thought that God designed and created hands-on, as it were, that is miraculously, Darwin’s deistic god created through unbroken laws at a distance. The important thing is that Paley saw ubiquitous adaptation. Following Paley, Charles Darwin saw ubiquitous adaptation, brought about by natural selection (Ruse 2017a).

The Later Years

Darwin discovered natural selection in 1838. A year or two later, he wrote a sketch of a theory based on this mechanism and shortly thereafter a fairly detailed exposition of 250 pages (Darwin and Wallace 1958). For reasons that are not clearly understood, even now, Darwin did not publish. Probably the reason is that given above, namely, that he realized that were he to publish, he would alienate himself from powerful members of the British scientific establishment. Darwin had no desire to be a pariah.

In any case, by this time he had fallen desperately sick. Early in 1839, Charles Darwin married his first cousin Emma Wedgwood, another of Josiah Wedgwood’s grandchildren. They set about having a conventionally large Victorian family. In the end there were ten children, seven of whom lived to majority. After the *Beagle* voyage, Darwin lived first in Cambridge and then in London. Thanks to family money, he and Emma were able to buy their own house, which they did in the Kentish village of Downe. There they rather cut themselves off from society, mainly mixing with neighbors and making extended trips to family members.

Quite why Darwin fell sick is still unknown. Some have suggested that it was the psychological burden of becoming an evolutionist (Desmond and Moore 1992). However, this seems unlikely because Darwin never truly seemed weighed down by this. Others have suggested that it was a physical ailment, Chagas’ disease caused by infection from an insect bite high in the Andes during the years of the *Beagle* voyage. More recently the suggestion has been made that Darwin suffered from lactose intolerance – an inability to digest milk products (Dixon and Radick

2009). This last hypothesis is given some credence by the fact that whenever Darwin went to health establishments, where he was put on a restricted diet, his health improved dramatically. It declined when once again he rejoined his family and started again eating the very rich diet that a comfortable middle-class family like the Darwins would have enjoyed daily.

What did happen was that Darwin slowly started to build around himself, mainly thanks to a very extensive correspondence (Darwin 1985–) – the Penny Post fortuitously came into being in 1840 – a group of younger scientists who would have far fewer objections and prejudices to evolutionary ideas. Prominent among these were the botanist Joseph Hooker and then a little later the morphologist and paleontologist Thomas Henry Huxley. For many years Darwin worked on an extensive study of barnacles (Darwin 1851a, b, 1854a, b). Finally, in the mid-1850s, he turned again to evolutionary studies and started writing up his work for publication.

Then, in the summer of 1858, he received from a young naturalist, out collecting in the Malay Archipelago, an essay containing virtually the same ideas that he had himself conceived 20 years previously (Wallace 1858). Spurred by the arrival of this essay, written by Alfred Russel Wallace, Darwin dropped everything and wrote for 15 months frenetically. Finally, in the late fall of 1859, his great work was published. *On the Origin of Species by means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* presented Darwin's thinking to the world.

We shall later look in some detail at the reception of Darwin's *Origin*. Suffice it here to say that, despite much controversy, very quickly people accepted the fact of evolution. Natural selection, however, was a different matter and much criticized. Darwin himself revised the *Origin* through some six editions. At the same time, he turned to other projects including a small book on orchids, issues to do with domestication, and then in the 1870s an array of works on plants including a study of insectivorous plants and another of climbing plants (Darwin 1862, 1868, 1875a,b). At the beginning of that decade, he also published

a major work on human evolution. *The Descent of Man and Selection in Relation to Sex* (1871) was nevertheless a rather odd book. Much of it was less about our own species and more about a secondary mechanism that Darwin had always endorsed (although hitherto not much discussed), so-called sexual selection. This is another matter we shall take up later, seeing why Darwin wrote as he did.

For all the controversy, Darwin was greatly respected as a scientist. Even those who differed most from him saw that he was a genius whose thinking had changed our perspectives entirely and irrevocably. He was also a thoroughly nice man, who was devoted to his wife and family, a good master to his servants, a loyal friend, and one who was always ready to offer help and advice (and, if necessary, a cash gift) to those in need. There is therefore little surprise that when Darwin died in 1882, by popular demand he was buried in England's Valhalla for its heroes, Westminster Abbey. There he lies for all eternity, next to the man whose work in physics Darwin had striven to emulate in biology, Isaac Newton.

Predecessors

The ancient Greeks did not believe in evolution. This refusal was not a matter of prejudice and certainly not a matter of religious prejudice. It was simply that they did not see how a blind process of law could lead to organisms. It was the great philosophers Plato and Aristotle who first realized that there is something distinctively design-like about the organic world, that adaptive nature which we saw in the last chapter Charles Darwin explained through his mechanism of natural selection (Ruse 2017a). Plato believed that there was a God who designs organisms (for that reason his position is often spoken of as one of "external teleology"). Aristotle believed that organisms have some kind of innate, vital force which leads to their design-like nature (for that reason his position is often spoken of as one of "internal teleology"). Either way, they thought that organic nature precludes creation through regular law. The pre-Socratic philosopher

Empedocles had argued that organisms come about through the cohesion of various parts, randomly. This is not really a full-blooded evolutionary position, but it is natural in the sense of proceeding according to and only to blind law. Aristotle was withering in his criticism, arguing with force that such a position is simply ridiculous. Evolution simply did not get off the ground in the world of ancient Greece.

The coming of Christianity did not help things very much either. For many years, Christians debated about whether or not they were committed to the books of the Old Testament. After all, this was the Jewish Bible, and the Jews had rejected their Savior. However, eventually, thanks particularly to the thinking of Saint Augustine around 400 AD, it was realized that in order to make sense of the Christian story of salvation, it was necessary to presuppose the Jewish story of creation, particularly inasmuch as it involved a fall of humankind necessitating the coming of Jesus. This meant that, with the acceptance of story of creation involving but 6 days around 6000 years ago, there were new reasons for rejecting evolution. Not that one has much sense that anyone had much inclination to accept evolution in the first place.

Progress

It was not until the beginning of the eighteenth century, the beginning of what historians now refer to as the Age of the Enlightenment, that we find the first stirrings of evolutionary speculation (Ruse 1996). By this time, although by no means universally widespread, there were more and more people starting to doubt the Christian story. The corrosive effects of philosophy had done its work. Although René Descartes died a good Catholic, he had supposed the possibility of an evil demon who makes all our beliefs false, including our Christian beliefs. For all that Descartes himself denied that this was definitive, and for all that his followers frenetically denied that this was definitive, a nagging worm of doubt continues to gnaw through the bud.

Then there were the quarrels between Christians themselves. Not just the differences between Protestants and Catholics, although these were

bad enough. There were also differences between Catholics and differences between Protestants. Indeed, in the century before, Britain had been torn apart by religious differences between Protestants. Even if one did not give up the belief in God entirely, increasingly there was space for speculation about whether any of these warring groups had a lien on the truth. Finally, voyages of exploration – particularly to Asia – had brought Europeans into contact with peoples who had sophisticated civilizations, including religions, yet who had never heard of Jesus Christ. Could it therefore be that Christian beliefs were just the cultural ephemera of a particular people rather than claims with deep insights into objective truth?

With Christianity no longer such an overwhelming force, there was space for evolutionary speculation. However, the problem of design or adaptation had not been solved. This was not to happen for a 150 years. If there was not yet a solution to adaptation, what then was sufficiently strong to motivate people into speculation about natural origins of organisms, the belief that there was a natural development from very primitive forms of to today's sophisticated forms? In a word, it was the ideology of *progress*.

The Christian believes in Providence. We can do nothing on our own. We are tainted, sinful, and condemned to death. Our only salvation lies through the blood of Jesus on the cross. Because of his great sacrifice, the possibility of eternal life is ours. To the contrary, the believer in progress claims that humans unaided can improve their lot through education, science, civic reform, and like activities. We can make Jerusalem here on Earth, without the direct aid of God. Although do note that back at the beginning of the eighteenth century, most progressionists were not atheists. They were rather deists (the position we have seen adopted by Charles Darwin). They believed that God set things in motion and then expected us to do things for ourselves.

Progress led directly to evolution. People believed in the possibility of upward change in the cultural realm. They then read this into the biological world. And then, equally promptly and in a circular fashion, they used biological progress

to confirm their beliefs in cultural progress! You might ask why people felt the need of progress to justify their evolutionism? The simple fact is that, at the beginning of the eighteenth century, there was nothing else on which to rest their beliefs. The fossil record was barely uncovered; the geographical distribution of organisms across the world was hardly hinted at; discoveries in morphology and embryology had to wait another century; theories of heredity were at the crudest level, to speak generously. Progress, however, was a heady ideology, and its enthusiasts were ever ready to extend it to other fields, most particularly the domain of the living.

One of the most interesting of the early evolutionists, coming toward the end of the eighteenth century, was Erasmus Darwin, British physician, inventor, agriculturalist, friend of industrialists, popular poet, and grandfather of Charles Darwin (Porter 1989; Ruse 1999). We are not quite sure exactly what sparked his interest in evolution, although it could be fossils that were being uncovered by laborers as they dug the channels and bored the tunnels for the canals that were now starting to crisscross England. What we do know is that he was an enthusiast for progress, an enthusiasm that extended to full-blooded support of the American Revolution (he was a good friend of Benjamin Franklin) and, in the early years, no less support for the French Revolution (until things started to go terribly wrong in that country).

Darwin wrote extensively about evolution, often in poetry. As can be seen from the following very typical passage, it was always evolution with a message. We start with the blob (what in those days was often called the “monad”). We end with the human (what in those days was often called the “man”).

Imperious man, who rules the bestial crowd,
Of language, reason, and reflection proud,
With brow erect who scorns this earthy sod,
And styles himself the image of his God;
Arose from rudiments of form and sense,
An embryon point, or microscopic ens!
(Darwin 1803, 1, 295–314)

Showing just how unsophisticated was Erasmus Darwin’s thinking compared to that of his

grandson Charles, there is virtually nothing in his voluminous writing about possible causes of evolution. There is however something that was to become particularly popular in the nineteenth century, although interestingly less so in Charles Darwin’s writings. This is the analogy between the development of the individual and the development of the group. Just as an organism grows from a speck up to the full-blooded adult, so likewise one supposes that the group grows from the speck to the sophisticated endpoint.

France

Many people read the poetry and prose of Erasmus Darwin. However, his influence was far eclipsed by that of the French, minor nobleman, Jean Baptiste de Lamarck. His *Philosophie Zoologique*, published in 1809 (the year of Charles Darwin’s birth), had tremendous influence, if only because it was often held up as a bad example of what not to do! Lamarck is famous for the mechanism named after him, Lamarckism – the inheritance of acquired characteristics. The blacksmith gets strong arms through working in forge, and, as a consequence, his son is born with strong arms even before he starts work. As it happens, this is but a minor part of Lamarck’s thinking, and it was a mechanism already endorsed by Erasmus Darwin (and, incidentally, was always to be endorsed as a secondary mechanism by Charles Darwin). Lamarck’s main picture of evolution was of an upward progressive drive, starting with chemicals in ponds which are the basis of the “spontaneous generation” of new organisms, thanks to lightning and other natural forces. Eventually, for Lamarck, as for everybody else, evolution ends with human beings (Burkhardt 1977).

Interestingly, however, since we today always associate evolution with a tree of life, Lamarck did not have this picture in mind at all. He believed rather in parallel lines of evolution, starting continuously down through the ages. Organisms follow the same predetermined paths, with occasional deviations due to the inheritance of acquired characteristics. Thus, whereas for someone like Darwin, if a species goes extinct, it will never return, for Lamarck, if a species goes

extinct, it is just a matter of time before it reappears all over again on a different, parallel, upward evolving line.

Lamarck was as enthusiastic about progress as was Erasmus Darwin. If you think about it, there had to be some reason why a nobleman would not merely survive the French Revolution but do well during it (as was the case with Lamarck). It was because he endorsed completely the philosophy which lay behind the tumultuous events. When the Revolution went wrong and led to the dreadful events of the Terror, both in England and in France, there was a revulsion against the ideology of progress. It was many years before it was to pick up again. And with enthusiasm for progress went any enthusiasm for evolution. In the early years of the nineteenth century, evolution was a much-derided notion. Note that this was not so much because it was regarded as anti-Christian, as because it was seen (truly) as an epiphenomenon on the back of a strongly disliked ideology.

No one opposed evolution more strongly than Lamarck's fellow Frenchman, George Cuvier (1813, 1817). He is rightly known as the father of comparative anatomy, thanks to the brilliant dissections he performed comparing and contrasting organisms of different species. He opposed evolution on many grounds, starting with the empirical. Thanks to Napoleon's expeditions to foreign lands, Egypt in particular, many specimens were being brought back to Paris. These included mummies of organisms long dead. When unwrapped and dissected, Cuvier could show that the mummified forms were of species which exist today. He therefore argued that there is no evidence of ongoing change (Coleman 1964).

Cuvier was also opposed to evolution on ideological grounds. He became a very important member of the French civil service. He was therefore deeply opposed to significant change and looked back to the years of the Revolution with horror. Progress leads to change; therefore, progress must be wrong. Evolution is connected to progress. Therefore, evolution must be wrong. Most overwhelmingly, however, Cuvier was opposed to evolution because he himself was

strongly committed to adaptation, the design-like nature of organisms. (He had studied the works of Aristotle in detail.) He could see no way in which blind law could lead to adaptation, or to use his term, to the "conditions of existence." In Cuvier's language, the conditions of existence preclude significant and ongoing development of evolution of organisms.

Britain

Cuvier articulated these ideas primarily in the second decade of the nineteenth century, and, until Darwin started publishing, for many this was definitive (Rudwick 1972). Cuvier was particularly influential in Great Britain. Although Cuvier was a Protestant, and thus more likely (than a Catholic) to base his thinking on the Bible, he was strongly opposed to the mixing of science and religion. The British felt no such delicacy. Although by the 1820s, none of the serious scientists were biblical literalists, they were all eager to see a close parallel between the science of origins and their reading of the Bible.

They realized by now that the Earth would be very much older than the 6000 years that one can calculate from the genealogies given in the Old Testament. But they were strongly committed to miracles, and they combined this with suggestions by Cuvier that there had in fact been upheavals in the geological past ("catastrophism"), to give a satisfying picture of origins. It was one which, as they thought, combined a serious interpretation of the now rapidly growing knowledge of the fossil record, with an active and ongoing role for the creative Christian God.

Naturally, these British scientists tended much more to the side of Providence than that of progress. However, by the 1830s, the horrors of the French Revolution were starting to recede in people's minds. At the same time, now that the Napoleonic wars were long gone, industry was starting to pick up. Expectedly, therefore, thoughts of progress started to emerge once again. And with thoughts of progress came thoughts of evolution. Most notably, in 1844, a Scottish publisher, Robert Chambers, writing anonymously, put out an evolutionary tract that rapidly became notorious for the daring nature of its speculations.

Vestiges of the Natural History of Creation left nothing to the imagination. Starting with thoughts of spontaneous generation – Chambers suggested that the frost ferns left by cold weather on windowpanes turned naturally into living plants – he saw an inevitable rise up from the primitive to the complex, from the monad to the man, and from the blob to the Britain. Combining a sketchy knowledge of the fossil record (most likely based on a misreading of Lamarck), with an equally sketchy knowledge of then-developing, Germanic studies of embryology, Chambers saw upward progress everywhere – in society, in the individual, and in the group.

Naturally enough, Chambers' ideas were strongly condemned by the British scientific establishment. Darwin's old geology teacher at Cambridge, Adam Sedgwick (1845), was particularly vehement, suggesting that such ridiculous ideas could only have been written by a woman and then taking back this suggestion because no woman could have speculated in so vile in fashion! Yet, for all the official opposition, it is clear that many in Britain and America and elsewhere responded favorably to Chambers' speculations (Secord 2000). One of the most interesting, for example, was the poet Alfred Tennyson. He was writing a long poem, *In Memoriam* (1850), dedicated to the memory of a friend who died too young. Despondent at the seemingly meaningless message of Lyell's *Principles* – things just keep going on and on without any progress – he then read Chambers. Tennyson found this particularly inspiring, even going to the limit of suggesting that perhaps his dead friend was a highly evolved being who had appeared before the time was right! A very odd idea indeed, but one that Tennyson's fellow Victorians (including Queen Victoria) found very inspiring.

By the 1850s, therefore, although Darwin was still sitting on his ideas, tucked away in the village of Downe, the idea of evolution was now becoming quite well known. It was still highly controversial and not at all accepted by professional scientists. It was seen, rightly, as the other side of the coin to hopes of social and cultural progress. In a way, therefore, one can talk of evolution as a "pseudoscience" (Ruse 1996, 2013a, b,

2016). It was not in any way a professional science, like physics and chemistry. And this was a status very much underlined by a new arrival in the field: Herbert Spencer.

A fellow Englishman of Darwin, Spencer, came from a much lower rung of the middle classes. He was not an establishment man. He felt no compunction about taking on the professional scientists of his day. Completely and utterly committed to the ideology of progress, Spencer started writing a great length in favor of evolution. Interestingly and almost paradoxically, Spencer (1852) hit on the idea of natural selection, but he rather dismissed it as trivial. For him, it was the Lamarckian process of the inheritance of acquired characteristics that was the main cause of evolutionary change. But truly, much like Erasmus Darwin 50 years before, Spencer was less interested in causes than in ideology. It was the upward chain, whether it be in culture or in biology, that really counted.

We see, therefore, that when Darwin published the *Origin of Species* in 1859, he was not working untilled ground. Ideas of evolution had been around for a 150 years. By the middle of the nineteenth century, they were well known and much discussed. However, they were not respectable. It was not so much that they were considered antireligious, although clearly there were tensions on this score – less on grounds of going against biblical literalists and more because evolution was seen as threatening thoughts of Providence – but because they were associated with a controversial ideology.

What therefore was needed to move the story forward was a work by a respected scientist, laying out a respectable case for evolution and its causes. It was this that Darwin set out to do in his *Origin*. In the next section, we turn to the case that he made.

The Origin of Species

In his autobiography, written toward the end of his life, Charles Darwin referred to the *Origin of Species* as "one long argument" (Darwin 1958). Let us take this comment seriously.

True Causes

The 1830s, the time when Darwin was coming to scientific maturity and making his great discovery, was a very important time in Britain for the methodology of science. Leading figures in the scientific community, most particularly the astronomer-philosopher John F.W. Herschel (1830, 1841) and the scientific polymath and historian and philosopher of science William Whewell (1837, 1840), were articulating and specifying the desiderata of the best kind of science. This was not an activity done in isolation. Men like Herschel and Whewell were working hard to professionalize British science and to make possible full-time careers in the field. It was necessary therefore to have an ideal against which work could be judged.

Naturally the labors of Isaac Newton were the great inspiration. His was the best science that had ever been produced. It followed naturally therefore that good science would share the characteristics of Newtonian science. But what were the characteristics of Newtonian science? Herschel and Whewell agreed that a scientific theory should be what we today call a “hypothetico-deductive system.” By this is meant an axiom system, where the initial premises or axioms are lawlike claims about the physical world. In the case of Newtonian mechanics, for example, one starts with the three laws of motion and the law of gravitational attraction, and then one can infer deductively Galileo’s laws about motions here on Earth and Kepler’s laws about the motions of planets.

It was also thought that good science is causal. After all, this was the great strength of the Newtonian system. It provided an underlying cause – gravitational attraction – to explain everything. Newton himself had referred to gravity as *vera causa* or “true cause.” There was some dispute about the exact nature of a true cause. Herschel (1830), who took a somewhat empirical attitude toward science, argued that a true cause is either something that one can sense directly or something for which one has good analogical evidence. For instance, he argued that we know there is a cause pulling the Moon toward the Earth because when we spin a stone at the end of the piece of string around our finger, we can feel the force down the string pulling the stone toward

us. Whewell (1840), who took a somewhat rationalist attitude toward science, argued that a true cause is not necessarily something we sense. It is rather something we infer from the evidence. If it can explain a range of phenomena, what Whewell called a “consilience of inductions,” then we have a true cause.

It should be noted that in the 1830s, this difference about true causes gave rise to a very lively debate. After a century of acceptance of Newton’s particle theory of light, scientific opinion had swung strongly toward Huygens’ wave theory. But why should one accept waves if one never sees them? Herschel offered all sorts of analogies with sound waves and water waves in order to convince people of the true-cause nature of light waves. Whewell dismissed all of these, arguing simply that light waves explain a broad range of evidence. For that reason alone, they should be accepted as a true cause. Geology also got involved in the debate. Herschel argued that Lyellian uniformitarianism, specifying as it did that we should explain the past in terms of causes of the present, satisfies the empiricists’ true-cause criteria. Whewell argued that catastrophism is a perfectly acceptable geological position. If there are geological phenomena, like mountain ranges, that demand the supposition of forces that we do not experience today, then it is acceptable to suppose them in order to get a full explanation. We have a true cause.

Artificial Selection

As an undergraduate, Darwin had known Whewell well, and then Darwin spent much time with Whewell in the early years after the *Beagle* voyage. He read Whewell’s writings with much care. Darwin had read Herschel’s little book on scientific methodology just before he left on the *Beagle* voyage and then met with Herschel during the voyage when the ship put into port in South Africa, where Herschel was spending several years mapping the heavens as seen in the Southern Hemisphere. Darwin therefore knew the positions of the two men. Eager to provide a theory that was methodologically sound, Darwin covered his options by trying to satisfy both the Herschelian empiricist demands for a true cause

and the Whewellian rationalist demands for a true cause! He left nothing to chance (Ruse 1975).

Thus, Darwin opened the *Origin* with a detailed discussion of selection as practiced by animal and plant breeders. In part, he was clearly doing this heuristically to lead the reader toward the main claims of his theory. He felt that if the reader could understand what is going on in the world of the breeder, then claims about natural selection and its evolutionary implications would be more readily grasped. In part, however, Darwin was preparing the way to use human selection as a form of support for natural selection. Darwin was arguing that the great successes breeders achieve, for instance, with pigeons, mirror the great success that natural processes achieve with wild animals and plants. In other words, the discussion of artificial selection was intended as a Herschelian, empiricist true cause. We have an analogy between something that we can see and work on ourselves and something that is not directly observable and that we must in some sense infer.

Note incidentally that Darwin presupposed (and indeed always presupposed) that natural selection is going to be a rather slow process. He never really envisioned the possibility that we might see natural selection actually taking place and having effects in an individual's lifetime.

Natural Selection

Next in the *Origin*, Darwin went on to introduce his chief mechanism of change. Nothing is possible without a constant supply of new variation. Darwin never had an adequate theory of heredity; but he was always fully convinced that, whatever the causes, any natural population of organisms will show considerable variation and that from generation to generation new variations will appear. (Darwin was always adamant that these variations are never directed toward an organism's needs. They are completely random, not in the sense of being uncaused – even though Darwin knew nothing about the causes, he was convinced that such causes do exist – but in the sense that they do not occur according to need.)

Then, with the variation, Darwin was ready to introduce first the idea of the struggle for

existence and then second the idea of natural selection. About the struggle, he wrote as follows:

A struggle for existence inevitably follows from the high rate at which all organic beings tend to increase. Every being, which during its natural lifetime produces several eggs or seeds, must suffer destruction during some period of its life, and during some season or occasional year, otherwise, on the principle of geometrical increase, its numbers would quickly become so inordinately great that no country could support the product. Hence, as more individuals are produced than can possibly survive, there must in every case be a struggle for existence, either one individual with another of the same species, or with the individuals of distinct species, or with the physical conditions of life. It is the doctrine of Malthus applied with manifold force to the whole animal and vegetable kingdoms; for in this case there can be no artificial increase of food, and no prudential restraint from marriage. (Darwin 1859, 63)

Then, Darwin went on to infer natural selection:

Let it be borne in mind in what an endless number of strange peculiarities our domestic productions, and, in a lesser degree, those under nature, vary; and how strong the hereditary tendency is. Under domestication, it may be truly said that the whole organization becomes in some degree plastic. Let it be borne in mind how infinitely complex and close-fitting are the mutual relations of all organic beings to each other and to their physical conditions of life. Can it, then, be thought improbable, seeing that variations useful to man have undoubtedly occurred, that other variations useful in some way to each being in the great and complex battle of life, should sometimes occur in the course of thousands of generations? If such do occur, can we doubt (remembering that many more individuals are born than can possibly survive) that individuals having any advantage, however slight, over others, would have the best chance of surviving and of procreating their kind? On the other hand we may feel sure that any variation in the least degree injurious would be rigidly destroyed. This preservation of favourable variations and the rejection of injurious variations, I call Natural Selection. (pp. 80–81)

Note that although these arguments are rather informal, Darwin was clearly intending some kind of hypothetical-deductive picture (Ruse 1971). We start with laws, for instance, about the tendency of organisms to increase in number geometrically and the impossibility of food and space supplies ever matching this tendency. We then go on to infer the struggle for existence. After this,

we include a premise about the existence of variation in all populations, combine it with the conclusion about struggle, and go on to infer natural selection. Nothing is very rigorous, but the intention is clear.

Along with natural selection, Darwin also introduced the secondary mechanism of sexual selection. Clearly influenced by practices in the breeders' world, Darwin divided sexual selection – resulting from competition between organisms of the same species for mates – into two kinds. First, there is sexual selection because of “male combat.” This occurs when males battle for mates, as when two stags fight over the herd. It leads to such physical characteristics as antlers and is obviously modeled on the results of breeders selecting for more ferocious fighting dogs or cockerels. Second, there is sexual selection because of “female choice.” This occurs when females choose, for their mate, what they regard as the most desirable male. It leads to such physical characteristics as the stupendous tail feathers of the peacock. It is obviously modeled on the results of breeders selecting for melodious songbirds and so forth.

Darwin also introduced what he called his “principle of divergence.” This is the process whereby organisms differentiate into new groups or species (meaning populations that are reproductively isolated from all other organisms). Darwin argued that it comes about because greater differentiation means greater opportunities to exploit the environment. If everything is exactly the same, then everyone is competing against everyone else. However, with differentiation, different organisms can exploit different ecological niches (to use more modern language). This leads to the tree of life, and in fact the only illustration given in the *Origin* is of the tree. It is given to back up the discussion of the principle of divergence.

Consilience

With the main mechanism now introduced, Darwin quickly covered some of the difficulties in his theory – most particularly, he acknowledged his ignorance about the true causes of heredity. Then, he was ready to apply the mechanism. Here it was the influence of William Whewell that was paramount. Darwin wanted to incorporate natural

selection in a consilience of inductions, showing it to be a true cause because it could explain different phenomena right through the spectrum of the life sciences. This is the project for the second half of the *Origin of Species*.

Darwin started with social behavior, most particularly focusing on the Hymenoptera, the ants, bees, and wasps. Darwin always recognized that behavior is as important in the struggle for existence as any physical feature. Hence, selection works to promote adaptive behaviors. Generally, this is of no great significance. The wolf gets faster, obviously, in order to catch the prey. The rabbit gets faster or better at maneuvering, in order to avoid the predator. However, Darwin saw that, when it comes to social animals, behavior starts to raise an interesting and difficult problem. Here we find that one animal will put much effort into promoting the well-being of another animal, as, for instance, when the workers in the hive devote all of their energies to the well-being of the queen and her offspring. Darwin always interpreted the struggle as being one organism against another, and hence he could not immediately see how it fits that selection could produce what we today call “altruism” (Ruse 2019a).

Hampered by the lack of an adequate theory of heredity, Darwin always had problems on this issue. He could see why the behavior of social insects is adaptive. For instance, he went to some considerable trouble to show that the hexagonal form of the honeycomb is by far the most efficient use of the wax. In other words, he showed that adaptation can extend from the organism itself to the objects the organism produces. (This is what the English biologist Richard Dawkins (1982) has called an “extended phenotype.”) But what about the behavior which serves the aims of others? One thing that Darwin was adamant about was that one could never simply have an organism working for the good of another, without either some kind of relationship or return. Eventually, Darwin decided that in some way it is appropriate to consider the group, the nest, and the hive, as one interrelated individual. Therefore, we should look upon the sterile worker less as an individual in its own right and more as a part of the whole. Just as in the individual human, the heart, lungs, and the brain

all work together because of the whole, so likewise in the hive the workers serve the cause of the whole.

Darwin then went on to discuss paleontology. You might think that this would be the easiest area of them all for an evolutionist to tackle. Darwin did not see things in this way. He was very much aware of such problems as gaps in the fossil record and no less aware that critics of evolution had seized on this as evidence that later forms (i.e., fossils found higher in the record) are not descended from earlier forms (i.e., fossils found lower in the record). He therefore devoted much time and effort to arguing that gaps in the fossil record are truly artifactual. Either they represent points at which we have incomplete knowledge, and linking fossils will be found later, or they represent points where we have incomplete knowledge and the gaps will never be filled because the needed fossilization never occurred. Either way, argued Darwin, it is more reasonable to suppose that the gaps are inadequacies in the record, rather than faithful reflection is what actually happened.

Obviously, paleontology was not just a matter of explaining deficiencies and problems. Going on the offensive, Darwin made much of the fact that we have a well-articulated progress in the record from more primitive forms to the complex forms we have around us today. More than this, Darwin pointed out that earlier forms often are more generalized, having features that are today shared by organisms that are otherwise very different. Darwin theorized that the earlier, generalized forms are the shared ancestors of today's diverse organisms. Darwin was aware that the early generalized forms are often similar to the embryos of today's forms. However, he never endorsed a simple picture of organisms going from the embryonic to the adult, in geological time as well as in individual time. Apart from anything else, this would seem to imply a kind of inevitable momentum to the course of evolutionary history. Darwin always thought that evolution, fueled as it was by natural selection, is a much more contingent and random phenomena. There is never any guarantee that one form will necessarily lead to another.

Darwin turned next to geographical distributions of organisms. Expectedly, given that this was the area that had first sparked his evolutionary inclinations – the reptiles and birds of the Galapagos Archipelago – Darwin felt very much at home here and argued strongly that one can explain distributions only on the evolutionary basis. One thing of which Darwin made much was the fact that the inhabitants of oceanic islands are almost always much closer in form to the inhabitants of the nearest continental mainland than they are to mainlands elsewhere. The Galapagos organisms look like South American organisms and are not at all like African organisms. Conversely, the organisms of the Canary Islands in the Atlantic, close to the coast of Africa, have a definite African tinge, rather than looking like inhabitants of South America.

From here, Darwin went on to look at systematics. It was in the eighteenth century that, thanks to the Swedish biologist Linnaeus, a proper order was imposed on the wide range of animals and plants to be found here on Earth. Among biologists concerned with classification, there was considerable debate about which criteria lead to natural or objective systems and which lead to artificial or subjective systems. However, by the middle of the nineteenth century, people were starting to get a real sense of what are truly natural orderings as opposed to just conveniences imposed on the organic world by the classifier. For instance, no one was about to deny that the sea mammals like whales are truly to be classified with other mammals rather than with fish or that flightless birds like the ostrich or emu belong with other birds, rather than with the mammals. Darwin proudly pointed out that there is a good reason for taking this classification as uniquely natural. It is simply that it represents the course of history. Whales are descended from other mammals and only at a distance from fish. The ostrich and the emu likewise are descended from other birds and not from mammals. Evolution through natural selection is the key to natural classification.

Next came morphology or anatomy. It had been known since Aristotle that there are isomorphisms between the bones of very different organisms. The forelimb of the horse, of the human, of

the seal, and of the mole – not to mention the wings of bats and birds – seem as if modeled on the same plan, even though the functions are very different indeed. Why should this be so? Was it simply that God somewhat capriciously decided to work from one pattern and molded everything accordingly? It was Darwin's argument that the similarities, now known as "homologies," are the result of evolution through selection. There was the ancestral, rather general, form, and then through the ages, selection turned the individual organisms to their different ends. One has a nice combination of what was known traditionally as "unity of type," meaning similarity of form, with "conditions of existence," meaning difference of function.

Drawing toward the end, Darwin turned with some pleasure to embryology. The German biologists, particularly Karl Ernst von Baer, had shown that there are significant similarities between the embryos of organisms very different as adults, the human and the chick, for example. Why should this be so? Darwin argued simply that it represents shared ancestry. Natural selection did not act to tear the embryos apart, because they are protected in the womb or the egg. Selection however did work on the adults.

At this point, Darwin made use of his Herschelian *vera causa* argument, showing that very similar phenomena can be found in the world of the animal breeder. Horse breeders and dog breeders care about the adults, not the young. Darwin found that, expectedly, the young of bulldogs and greyhounds are very much more similar than the adults. Likewise, the young of cart horses and racehorses are very much more similar than the adults. This was perfect confirmation of Darwin's position, especially since the breeders themselves had denied that this was so!

The consilience was completed. Darwin had shown how evolution through natural selection explains across the spectrum of the life sciences. Conversely, the explanations point to the truth of the Darwinian true cause, natural selection:

It is interesting to contemplate an entangled bank, clothed with many plants of many kinds, with birds singing on the bushes, with various insects flitting about, and with worms crawling through the damp

earth, and to reflect that these elaborately constructed forms, so different from each other, and dependent upon each other, in so complex a manner, have all been produced by laws acting around us. These laws, taken in the largest sense, being Growth with Reproduction... a Rate of Increase so high as to lead to a Struggle for Life, and as a consequence Natural Selection entailing, a Divergence of Character and the extinction of less-improved forms. Thus, from the war of nature, from famine and death, the most exalted object we are capable of conceiving, namely, the production of the higher animals, directly follows. There is grandeur in this view of life, with its several powers, having been originally breathed into a few forms or into one; and that, whilst this planet has gone cycling on according to the fixed law of gravity, from so simple a beginning endless forms most beautiful and most wonderful have been and are being, evolved. (pp. 489–490)

Reception

John Murray, Charles Darwin's publisher, printed 1250 copies of the *Origin of Species*. Darwin was worried that many would be left over. Murray knew better. On the first day of his half-yearly sale of books to booksellers, the *Origin* sold out completely. At once, Darwin was ordered to start preparing second edition. It was almost as if the world had been waiting. Evolution was a much-discussed, highly controversial idea. What was needed was a definitive work by a major scientist. The *Origin* was that work and Darwin was that scientist.

Fact Not Theory

There was certainly controversy. Famous, even today, is the clash between Thomas Henry Huxley, representing the side of science, and Bishop Samuel Wilberforce of Oxford, representing the side of religion. In the summer of 1860, they debated at the annual meeting of the British Association for the Advancement of Science, at Oxford. Supposedly, Wilberforce asked Huxley if he was descended from monkeys on his grandfather's side or his grandmother's side. Supposedly, Huxley responded that he would rather be descended from a monkey than from a Bishop of the Church of England! The story is almost surely

apocryphal (Lucas 1979). But even myths tell truths. Darwin's theory of evolution through natural selection did cause a major upheaval in Victorian Britain.

As mentioned in section "[The Man and His Life](#)," very quickly most people accepted the fact of evolution. It became almost commonsensical. Darwin had accumulated so much evidence; it became difficult to deny that organisms had emerged slowly and gradually by natural processes. And in fact, to tell the truth, most people were happy to accept evolution. It has been explained that, even when Darwin was a young man, people were well on the way to interpreting the early chapters of the Bible metaphorically. With exceptions to be discussed later, it was realized that the Earth is very old and most people are happy to opt for natural origins rather than miracles. In 1866, the examinations for students at the University of Cambridge even went so far as to say that the truth of evolution should be assumed and examinees should focus on discussion of causes. While it is hard to be definite about these things, and of course there are going to be exceptions to every rule, by about 1870 very few wanted to deny evolution. This applied even to religious people. They probably wanted to make some special exception to human souls, but natural origins was now a given (Roberts 1988).

As also mentioned, the fate of natural selection was very different. No one wanted to deny its existence completely. However, there were few who wanted to give it the importance that Darwin proposed in the *Origin* (Bowler 1983). For example, although Huxley was happy to debate evolution with everybody and anybody, he never was much of an enthusiast for natural selection. To the contrary, he thought that every now and then, there are jumps – what were called “saltations” – taking organisms from one form to another, in just one generation. Others continued to stress the importance of Lamarckism, the inheritance of acquired characteristics. We have seen that Herbert Spencer fell into this category. Yet a third group wanted to put some kind of God-driven guidance into the new variations. Asa Gray, the professor of botany at Harvard University and Darwin's great North American supporter, was

one who thought this way. And we find another set, often inspired by Germanic thinking, who thought that there is a kind of momentum to evolution, driving it ever upward. These were the people who were particularly keen on analogies between the development of the individual and the development of the group. Most famous was the German morphologist Ernst Haeckel, who incorporated these ideas in to his famous “biogenetic law”: “ontogeny recapitulates phylogeny” (Richards 2008).

Against Selection

Why was there this downplaying of natural selection? In part, it was negative. Darwin thought that the most important characteristic of the organic world is that it is highly adapted. Natural selection was promoted to explain this fact. However, by the 1850s, biologists were far less impressed with adaptation. They had moved away from naturalistic studies of organisms in the wild, the sorts of things that Darwin was looking at when he was in South America during the time of the *Beagle* voyage, to laboratory studies of dead organisms on the dissecting table. The big questions in the 1850s centered on homology and structure, that is to say unity of type. Questions of design and success in life, that is to say questions of conditions of existence, were relegated to the relatively unimportant. So in a sense, by the time the *Origin* was published in 1859, many thought that natural selection was a solution to a nonexistent problem.

In part, the rejection of natural selection was positive. It was felt that there were insuperable difficulties to its acceptance. For a start, as has been pointed out earlier, Darwin had no adequate theory of heredity. Without this, natural selection was always vulnerable. If you cannot show why new variations will be passed on from generation to generation without being diluted, then no matter how effective selection may be, there's always the danger that it will fade away in two or three generations. This was the objection of the Scottish engineer Fleeming Jenkin. Even Darwin thought he scored a good point (Hull 1973).

There was an even bigger obstacle in the way of natural selection. The physicists had devised various ways of calculating the age of the Earth.

These were based on such factors as the heat received on Earth from the Sun, the saltiness of the sea, the heat expected from the Earth's core based on increasing temperatures as one goes deeper and deeper into mines, and other such phenomena. The general estimate was that the Earth cannot be more than 400 million years old and that it could be as young as 25 million years. The favored middle figure was about 100 million years. But this was felt to be far too short a time for such an allegedly slow process as natural selection. Hence, other mechanisms would be needed (Burchfield 1975).

Of course, today we know that the physicists were wildly inaccurate in their calculations. They were ignorant of the warming effects of radioactive decay. Today it is thought that the universe as a whole is about 15 billion years old and that the Earth is about 4 1/2 billion years old. The earlier life seems to have appeared about 3 3/4 billion years ago. At the time of the *Origin*, however, this was unknown and consequently was a major impediment to the acceptance of natural selection.

Darwin was convinced that he was right. Interestingly, although in the light of what we have seen perhaps predictably, whenever he was challenged on selection, he invoked the example of the wave theory of light, arguing that since we accept it, we should on the same grounds accept selection. Also, at every opportunity, he seized on new, favorable information. For instance, early in the 1860s in Germany, they discovered the first specimens of archaeopteryx, the transitional fossil between the birds and reptiles. Darwin introduced this organism into one of the later editions of the *Origin*, trumpeting it as proof that gaps in the fossil record are a function of ignorance rather than genuine absence. Again, a young naturalist and sometime traveling companion of Alfred Russel Wallace came up with a very ingenious, selection-based explanation of the mimicry that one often finds between different species of butterflies (Bates 1863). Henry Walter Bates argued that some butterflies are naturally poisonous and thus have an adaptation against their predators, the birds. Other butterflies have no such poisonous taste, but have found it advantageous to mimic the poisonous butterflies. In a series of ingenious

experiments, Bates showed how one could reasonably infer that this was the end result of a selective process. Darwin was very excited by this explanation, and it found its way into a later edition of the *Origin*. Although, somewhat curiously, in line with what has been said earlier about Darwin's never believing that selection can actually be seen in action, he rather relegated to a secondary position at the end of the book. One might have thought that it would have been introduced early and made prize specimen in the evidential gallery. One has the nasty suspicion that Darwin himself was not entirely out of line with the non-Darwinians after the *Origin*! After all, his major contribution to regular biology had been on barnacles, where adaptation often is a bar to discerning morphology.

Interestingly, Bates was not alone, and in the years after the *Origin*, many working on insects turned to selection for explanation. Of particular interest was industrial melanism, where butterfly and moth wings get darker to provide better camouflage against predating birds against the ever-increasingly soot-covered trees. One enthusiast even wrote to Darwin about this.

My dear Sir,

The belief that I am about to relate something which may be of interest to you, must be my excuse for troubling you with a letter.

Perhaps among the whole of the British Lepidoptera, no species varies more, according to the locality in which it is found, than does that *Geometer*, *Gnophos obscurata*. They are almost black on the New Forest peat; grey on limestone; almost white on the chalk near Lewes; and brown on clay, and on the red soil of Herefordshire.

Do these variations point to the "survival of the fittest"? I think so. It was, therefore, with some surprise that I took specimens as dark as any of those in the New Forest on a chalk slope; and I have pondered for a solution. Can this be it?

It is a curious fact, in connexion with these dark specimens, that for the last quarter of a century the chalk slope, on which they occur, has been swept by volumes of black smoke from some lime-kilns situated at the bottom: the herbage, although growing luxuriantly, is blackened by it.

I am told, too, that the very light specimens are now much less common at Lewes than formerly, and that, for some few years, lime-kilns have been in use there.

These are the facts I desire to bring to your notice.

I am, Dear Sir, Yours very faithfully,
 A. B. Farn
 Letter from Albert Brydges Farn on November
 18, 1878 (Darwin 1985-, 26, 440)

Instead of bringing out a new edition of the *Origin* with this letter facing the title page, Darwin seems not to have replied to the writer, adding weight to the belief that selection studies were simply not regarded as fully professional. Farn was a civil servant, and Bates spent his career as an administrator for the Royal Geographical Society. Darwin was not unappreciative of Bates – he got him the job – but Darwin never really seems to have internalized this sort of approach into his science (Ruse 2017a, 2018, 2019a, b).

Human Beings

In the *Origin*, Darwin said very little about humankind. Before all discussions were swamped by a tsunami of controversy about human origins, he wanted to get the basic principles of his theory out in public. Hence, he made only a throwaway comment at the end, about the significance of his theory for our own species. And he did this simply that he not be accused of cowardice on the subject.

Reticence should not be confused with hesitation. There was no doubt in Darwin's mind about the applicability of his theory to *Homo sapiens*. Interestingly, in his private evolution notebook for 1838, the very first mention we have of natural selection in action is a speculation about how the human brain will grow under the actions of this mechanism. Darwin was always convinced that humans are part of the natural order of things. This fit in nicely with his deistic beliefs and probably was connected experiences on *Beagle* voyage. On a previous trip, the captain of the *Beagle*, Robert FitzRoy, had brought back to England three of the natives of the southernmost tip of South America, the already-mentioned Tierra del Fuego. These were being returned on the voyage that Darwin took. When they were put ashore, within a week or two, to the horrified amazement of the *Beagle*'s crew, these natives reverted quickly back to what the Victorians called "savages." It convinced the ship's naturalist that we humans are very close to animal nature. He learnt a lesson that he never forgot.

Darwin was reticent on the subject of human origins; others were far less cautious. Huxley, in particular, was pushing a materialist philosophy and made the natural origins of humankind a major plank in his world picture. He wrote a little book, *Man's Place in Nature* (1863), arguing strongly for our animal nature. Others did much the same. Yet, although Darwin was responsible for one of the biggest controversies of his age, by nature he always shrank back from violent confrontations. He preferred to tend his illnesses in the security of his family, tucked away in the Kentish countryside. Probably, he would have been happy to have left others carry completely the discussion about humankind. However, it was not to be. Alfred Russel Wallace, the co-discoverer of natural selection, spent the 1860s becoming more and more enthusiastic about spiritualism. Finally, he took to arguing that humankind could only have come about thanks to the intervention and guidance of spirit forces. In other words, Wallace (1870) gave up entirely on a naturalistic explanation of our origins.

Darwin was appalled. He thought, with good reason, that Wallace was doing his best to destroy the credibility of natural selection. Something had to be done. But what? The trouble was that, spiritualism or not, Wallace brought forward some good arguments against the all-conquering power of natural selection. In particular, he pointed out that many human characteristics almost certainly did not come into being thanks to natural selection. Human hair was one example, and human intelligence was another. Although Darwin had seen many natives during his years in and around South America, he had never really lived with them. Wallace, to the contrary, had done just that. He had spent some 4 or 5 years in South America collecting butterflies and then a year or two later went East to the Malay Archipelago, where he spent even more time.

Without the unlimited funds of a Darwin, Wallace had to live in a fairly simple way. This meant sharing accommodations with the native people that he encountered. Wallace was impressed by the extent to which the natives obviously underutilized their potential brain power.

Although he was sure that native people could be as intellectually developed as Europeans, in fact this rarely happens. Hence, pointed out Wallace, it seems that for many years humans had a huge amount of unused brain capacity. This is something that could hardly have been brought about by natural selection, because having a brain is clearly something which is biologically costly. Protohumans could not have afforded such a luxury, at least not on naturalistic grounds. There had to be a reason. Wallace's conclusion was that spirit forces prepared the brain's early form, something waiting to be used when European civilization got underway.

The Descent of Man

It is at this point that Darwin turned to sexual selection for help, and it is this that explains the already-mentioned rather odd balance of Darwin's book on humankind, *The Descent of Man*. Darwin argued that many human characteristics are indeed inexplicable on natural selection; however, they can be readily explained thanks to sexual selection. In particular, Darwin argued that human intelligence is something that could readily have emerged through a struggle for mates, whether this be through combat of males or the selection of females of the men that they preferred. To be frank, one rather feels that Darwin got carried away by this topic. He discussed sexual selection in the *Descent* very much in its own right and at great length. However, the overall intent was to develop and present a secondary mechanism, something that could then explain important aspects of human nature.

The *Descent* appeared in 1871. It is not, and does not pretend to be, a work of the staggering originality of the *Origin of Species*. By the time Darwin was writing, there had been a decade of inquiry and speculation about human nature and its evolutionary origins. Darwin, therefore, was able to draw extensively on the work of others. Nevertheless, the book could only have been written by the author of the *Origin*. Darwin gave a very detailed exposition of the path of human origins as best known at the time. At the same time, he tried to show how natural selection could account for the main aspects of our evolution.

(Although Darwin was to make much of sexual selection in explaining human evolution, he never doubted that natural selection overall was the main force of change.)

Expectedly, given his fascination in the *Origin* with social evolution in the insects, the *Descent* devoted considerable attention to questions of social evolution in humankind. Darwin was particularly keen to show that our moral sense is something which comes naturally and does not demand a supernatural explanation. Following the discussion almost exactly from earlier years, Darwin saw morality as something developing within a tribe and a tribe itself he considered to be something akin to the nest of the ants or the hive of the bees. Darwin never deviated from his belief that ultimately selection is always between individuals and hence adaptations must rebound to the benefit of individual, and only secondarily to groups, if at all (Ruse 2012; Richards and Ruse 2016).

Darwin also touched upon religion, although briefly. By this stage of his life, like so many Victorians, he rather inclined to think that traditional religion is superstition. As a discreet Englishman, he did not come out and say this bluntly. But his treatment shows that this was basically his position. He looked upon religion as something of a by-product, brought about by incidental factors. For instance, he likened religious responses to nature to the excitement shown by one of his dogs when a parasol fluttered in the wind. It was not so much that Darwin was anti-religious but that basically he no longer found religion particularly relevant to his life, nor could he see much reason why it had to be relevant to the lives of others.

Although Darwin was not the fanatic about progress that had been so often true of earlier evolutionists and was still true of people like Herbert Spencer, it is clear from the *Descent* that Darwin believed fully that we humans have come out top. Moreover, among humans, the Europeans have come out best of all. In later editions of the *Origin*, Darwin speculated that a form of progress could occur because better quality organisms are always beating out lesser quality organisms. Overall, this could accumulate until one gets

some kind of progress approaching absolute value. There is not much explicit discussion of any of this in *The Descent of Man*, but it is certainly presupposed.

Interestingly, however, Darwin was not much inclined to think that today Europeans triumph over native races because of their superior fighting or intellectual characteristics. It is rather because Europeans have better natural immunities to diseases than do natives. Hence, when the two groups mix and interact, it is much more likely that native peoples will succumb to common diseases like measles. It is clear also that Darwin thought that sexual selection will play a role here. Better quality males will emerge, thanks to the struggle for mates. Also, more attractive females will emerge thanks to selection for beauty and related features. Although Darwin was a great revolutionary, as I said earlier he was no rebel. This is shown very clearly by his natural assumptions about the superiority of Europeans with the natives and even more by his unquestioned belief that males are far more intelligent on average than of females, whereas females compensate by being creatures of emotion and sympathy. Brains for men; hearts for women!

From Pseudoscience to Popular Science

Charles Darwin entered the scene when evolution was a pseudoscience. Given his careful attention to the methodologies of his day, it had obviously been Darwin's hope that in the *Origin* he would elevate evolutionary studies to the level of a professional science, like physics and chemistry. He wanted natural selection could be a fruitful mechanism of inquiry. However, he failed in this aim. He convinced the world that evolution as a fact is true. What he did not do was convince his fellow professional scientists that natural selection is an active and valuable tool of inquiry, giving us insights into the nature of organisms and their histories. In fact, as we have seen, Darwin himself was a little reserved on this matter. One could have developed a whole field of selection studies – Darwin himself could have funded a group working in such a field – but he seems to have been rather cautious and unenthused. At most one can

say that one had professional science being done by nonprofessionals.

More generally, after Darwin, evolution was very much a topic to be found and discussed in the general domain. One major sphere of activity and influence tended to be in the new museums of natural history that were being built in Britain, on the continent, and particularly in the great cities of the United States. It was there that one went to see the wonderful panoramas of biological change, from primitive forms up through lesser animals until one reaches the primates with humans out peak. With the fabulous finds of fossil dinosaurs in the Western United States and Canada in the second half of the nineteenth century, museums became focal points of immense popular interest.

Natural selection – and even more sexual selection – also had a big presence in the popular domain. In literature – novels and poetry! From the first, creative writers seized on Darwin's mechanisms and showed how they work in human affairs (Ruse 2017b) or canine affairs, as is shown in Jack London's classic *The Call of the Wild*:

His teeth closed on Spitz's left fore leg. There was a crunch of breaking bone, and the white dog faced him on three legs. Thrice he tried to knock him over, then repeated the trick and broke the right fore leg. Despite the pain and helplessness, Spitz struggled madly to keep up. He saw the silent circle, with gleaming eyes, lolling tongues, and silvery breaths drifting upward, closing in upon him as he had seen similar circles close in upon beaten antagonists in the past. Only this time he was the one who was beaten.

There was no hope for him. Buck was inexorable. Mercy was a thing reserved for gentler climes. (London 1903, 24)

Interestingly, London – like most of the writers on the topic – saw fully that selection does not just lead to the success of the brute, the killer. It can – as Darwin stressed – lead also to harmony and altruism. No sooner has Buck taken over the pack than he turns into a headmaster! Everyone now benefits from Buck's success, dogs and men. “Highly as the dog-driver had forevalued Buck, with his two devils, he found, while the day was yet young, that he had undervalued. At a bound Buck took up the duties of leadership; and where

judgment was required, and quick thinking and quick acting, he showed himself the superior even of Spitz, of whom Francois had never seen an equal" (26). And slackers are pulled back into line:

Pike, who pulled at Buck's heels, and who never put an ounce more of his weight against the breast-band than he was compelled to do, was swiftly and repeatedly shaken for loafing; and ere the first day was done he was pulling more than ever before in his life. The first night in camp, Joe, the sour one, was punished roundly – a thing that Spitz had never succeeded in doing. Buck simply smothered him by virtue of superior weight, and cut him up till he ceased snapping and began to whine for mercy. (26)

In poetry too, this poem, "Natural selection," by the young woman (in her sex's interest in Darwinism, she was by no means atypical) Constance Naden, is really about sexual selection. But it makes the point.

I HAD found out a gift for my fair,
I had found where the cave men were laid:
Skulls, femur and pelvis were there,
And spears that of silex they made.

But he ne'er could be true, she averred,
Who would dig up an ancestor's grave—
And I loved her the more when I heard
Such foolish regard for the cave.

My shelves they are furnished with stones,
All sorted and labelled with care;
And a splendid collection of bones,
Each one of them ancient and rare;

One would think she might like to retire
To my study—She calls it a "hole"!
Not a fossil I heard her admire
But I begged it, or borrowed, or stole.

But there comes an idealess lad,
With a strut and a stare and a smirk;
And I watch, scientific, though sad,
The law of selection at work.

Of Science he had not a trace,
He seeks not the How and the Why,
But he sings with an amateur's grace,
And he dances much better than I.

And we know the more dandified males
By dance and by song win their wives—
'Tis a law that with *avis* prevails,
And ever in *Homo* survives.

Shall I rage as they whirl in the valse?
Shall I sneer as they carol and coo?
Ah no! for since Chloe is false
I'm certain that Darwin is true
(Naden 1999, 207–8)

In short, although there was some limited amount of evolutionary morphology in the universities, by and large evolution through selection was not a science for the professional scholar. In the public domain, the story was very different. Thanks to Darwin, evolution was transformed from a pseudoscience to a popular science, for all that it had yet to achieve the status of full-blooded professional science.

Today' Science

After the *Origin*, probably the most important event in the history of evolutionary theory was the work in the 1860s, on the principles of heredity, by the Moravian monk, Gregor Mendel, or, perhaps more pertinently, the rediscovery of his work at the beginning of the twentieth century (Provine 1971). People often regret that Darwin and Mendel were working independently. If only they had got together and collaborated, then, much earlier than it was, the course of evolution would have been advanced significantly. Or, at least, this is the supposition. In fact, Mendel was working on rather technical questions about plant breeding (Stern and Sherwood 1966). It is highly improbable that had Darwin read his work he would have grasped the full significance. Conversely, Mendel did in fact read the *Origin of Species*. But he never once thought that what he himself was doing contributed to the story. Instead, from Mendel's marginalia we can infer that the big question that the *Origin* posed to him was whether or not it was a theory acceptable to a Catholic priest!

Becoming a Professional Science

Once rediscovered, Mendel's ideas were developed quickly and fused with a growing understanding of the physical nature of the organic cell. By the middle of the second decade of the twentieth century, Thomas Hunt Morgan and his

students at Columbia University in New York City had developed the so-called classical theory of the gene (Allen 1978). This theory sees the unit of heredity, the gene, as a particle on one of those long, stringlike entities, chromosomes, in the center of the cell, the nucleus. Chromosomes come in pairs, so genes are paired, and the time of reproduction one of each gene pair gets passed on through the sex cells to the next generation. The important thing is that the genes remain unchanged from generation to generation, changing only occasionally when they spontaneously “mutate” from one form to another. As Darwin supposed, mutation is random in the sense that it does not occur according to need, but it is not random in the sense of being uncaused. Today, much is known about the physical causes of mutation.

Perhaps expectedly, when Mendelian genetics was first rediscovered, its supporters inclined to think that it offered a rival to a Darwinian picture of evolution through natural selection. For a while, there was a bitter controversy between the Darwinian “biometricians” and the Mendelian “geneticists” (Olby 1988). However, by the second decade of the century, biologists were starting to see that Darwinian selection and Mendelian genetics are not contradictories but complementary parts of the whole picture. Because selection is something which works only on populations not on individuals, it was necessary to generalize Mendelian genetics to cover populations. This was done by two researchers after whom the key premise, the Hardy-Weinberg law, is named.

In Newtonian mechanics, his first law (that bodies remain at rest or in uniform motion unless acted upon by a force) acts as an equilibrium law, against which one can now introduce intervening or distorting forces. In “population genetics,” the Hardy-Weinberg law has the same function (Ruse 1973). This law essentially tells you that in large populations with no impinging forces – no selection, no mutation, or no immigration or emigration in or out of the population – the gene ratios will stay constant. In other words, it is the background equilibrium against which one can now introduce distorting forces like mutation and selection.

Around 1930, several mathematically gifted biologists developed this theory, something that is the basis of evolutionary thinking even to this day. In England particularly important were Ronald A. Fisher (1930) and J. B. S. Haldane (1932). In America particularly important was Sewall Wright (1931). As it happens, although their theorizing was formally equivalent, the English and the Americans (Fisher and Wright particularly) had very different visions of the evolutionary process (Provine 1986). For Fisher, it was always Darwin’s mechanism first and foremost, as he saw populations being molded and shaped by natural selection occurring on working on new variations, mutations. For Wright, things were rather more complex. Although he gave selection an important role in his “shifting balance theory” of evolution, random forces or effects were highly significant. Wright pointed out that, in small populations, the vagaries of breeding might be expected to overcome weak forces of selection. Hence, one might get ratios of genes “drifting” from one level to another. Wright believed that this is very significant in the evolutionary process and that, consequently, whereas Fisher with his selectionism saw adaptation everywhere, Wright was much more inclined to think that many features are adaptively neutral.

We have here echoes of the differences at the time of the *Origin*, with Darwin ultra-keen on adaptation and Huxley somewhat indifferent.

With the theory spelt out, the empiricists moved in. In England, particularly important was the Oxford biologist E. B. Ford (1964). He was the founder of the school of evolutionists which he labeled “ecological genetics.” Ford and his collaborators worked extensively on organisms that reproduce rapidly, including butterflies, moths, and small invertebrates like snails. Particularly noteworthy were some studies done in the 1950s by A. J. Cain (1954) and Philip Sheppard (1958) on the ways in which snail-shell colors and markings provide adaptive camouflage against predators, mainly thrushes. In the United States, the most important figure was the Russian-born geneticist Theodosius Dobzhansky. He was the author of *Genetics and the Origin of Species* (1937), a work in which he showed how Wright’s

shifting balance theory could be applied to many problems, particularly variations in *Drosophila* (fruit flies). Dobzhansky was also important for encouraging researchers in other fields to turn to evolutionary problems. Significant were the German-born systematist Ernst Mayr, author of *Systematics and the Origin of Species* (1942); the paleontologist George Gaylord Simpson, author of *Tempo and Mode in Evolution* (1944); and then a little later the botanist G. Ledyard Stebbins, author of *Variation and Evolution in Plants* (1950). Thanks to the work of these people, their collaborators and associates, and above all their students, by the hundredth anniversary of the *Origin of Species* in 1959, finally Darwin's work had matured into a fully professional science. In England, it was generally known as "neo-Darwinism," and in America, paying tribute to Mendel as well as Darwin, as the "synthetic theory of evolution" (Maynard Smith 1958; Ruse 2006).

The last half-century has seen a huge amount of work, both theoretical and empirical, tackling evolutionary problems from a Darwinian perspective. To give a flavor of what has been produced, it will be convenient to follow the pattern of the argument in the *Origin*. In that way, we will get an idea not only of what has been done but how things have advanced since Darwin himself. Generally, the Darwinian belief in the ubiquity of adaptation has prevailed, although we shall see that critics do persist.

Artificial and Natural Selection

We start with artificial selection. There are now a many case studies showing how continued, systematic selection by human beings can have huge effects on the genetically based nature of animals and plants. To take but one example, justly famous is very long-term study (it started back in 1896) done at the University of Illinois on the oil content of corn (what Europeans call maize). At the beginning of the study, the oil content was in the range of 4–6%. By the end of the study, in the 1970s, thanks to continued selection, the oil content had increased threefold to around 16%. This is change in itself (Mangelsdorf 1974; Dudley 1977). However, one objection that

Darwin's contemporaries (notably Thomas Henry Huxley) often made was that artificial selection seems never to lead to new species, meaning separate groups of organisms unable to interbreed. Today we have such cases. One experiment started with yellow and white varieties of corn. Selecting intensely for individuals that mated with others of the same color, in a very few generations, experimenters produced two groups with very little cross-fertilization. It turned out that there was a good reason for this. The white variety flowered at an earlier time than the yellow variety, and hence pollination of the two varieties was kept quite separate.

Moving on to the key part of the *Origin* where natural selection was introduced, what evidence do we have today of this mechanism in action? It will be remembered that Darwin himself inclined to think that we would never have any direct observations of natural selection changing organisms. Remember though, although I am not sure that Darwin picked up on the significance, late in his life, one of his correspondents drew his attention to what today is probably the most famous example of evolution in action, so-called industrial melanism. Butterfly collectors cherish exceptional or strange forms. By the middle of the nineteenth century, in England, it was becoming clear that increasingly in some species of butterfly, there were dark or so-called melanic forms. Darwin's correspondent hypothesized that there is a reason for this: industrial pollution. By the end of the nineteenth century among students of butterflies and moths, industrial melanism was a well-recognized phenomenon, and researchers realized that natural selection was at work (Tutt 1891). However, it was not until the middle of the twentieth century that one of Ford's groups of ecological geneticists, H. B. D. Kettlewell (1973), working in areas around Oxford, finally showed definitively that the melanic forms of moths and butterflies are indeed sustained by selection for camouflage. Presciently, Kettlewell suggested that were pollution ever to be controlled, we might expect to find that the melanic forms would decline and the normal forms regain their ascendancy. Since the 1950s, in Britain there has been major overall drive to reduce air

pollution. Trees today are far less blackened than they were 50 years ago. And as predicted, we find that the lighter forms of butterflies predominate and the melanic forms are consequently significantly lower. A beautiful case of natural selection is being observed in action (Majerus 1998).

We need not dwell here at any length of the discoveries about heredity. We have seen already in this entry that the field has been transformed since the days of Charles Darwin. Of course, genetics itself has not stood still. The major event after the rediscovery of Mendelian genetics was obviously the deciphering of the structure of the DNA molecule in 1953, by the American James Watson and the Englishman Francis Crick. The double helix led to a huge amount of work uncovering the basic secrets of heredity at the molecular level. Repeating an earlier pattern, at first it was thought that the new genetics was a rival to Darwinian selection; but then, again repeating an earlier pattern, it was seen how in major respects molecular biology is a handmaiden to the evolutionist. Most notably, in the 1960s, the geneticist Richard Lewontin and his associates used their knowledge of molecular biology, combined with new experimental techniques, to peer in much greater detail into the nature of variation in wild animals and plants. It will be remembered how important it was for Darwin's theory that there be such variation. In its absence, natural selection is ineffectual. Using "gel electrophoresis," Lewontin and others showed just how much variation there is, leading to a level of understanding quite beyond anything that Darwin offered in the *Origin of Species* (Lewontin 1974).

Consilience

What of the consilience of inductions? We have seen how this was a crucial part of the argumentation of the *Origin*, as Darwin strove to show that natural selection is a true cause. Simply put, the consilience as such exists unchanged in today's evolutionary studies. But it has been transformed completely by new findings and new theories that have enriched our understanding of the different areas of the life sciences. Following Darwin, let us go briefly through social behavior, paleontology,

biogeographical distributions, systematics, morphology, and embryology.

The study of the evolution of social behavior has seen explosive growth in the past half-century. "Sociobiology," as the field is now called, has many, many exciting discoveries to report. Thanks to the work of leading exponents – particularly William Hamilton (1964a, b) in England and Edward O. Wilson (1975) in America – we have a detailed and sophisticated grasp of how natural selection has shaped and molded the behaviors of organisms in groups (Ruse 1979). Particularly important was Hamilton's insight that organisms need not reproduce directly themselves. It is enough that close relatives (that is to say, organisms sharing the same genes) reproduce, so one does it by proxy as it were. "Kin selection" has proven to be a very powerful tool of investigation (Maynard Smith 1982). Sociobiologists have been able to analyze the relationships existing within groups of ants, bees, and wasps (Hymenoptera). They point to the fact that sterile workers share the same genes as their fertile nest mates, and hence, inasmuch as they help these nest mates to reproduce, they are themselves reproducing, in the sense of passing on copies of the genes. In other words, today we can go a step beyond Darwin and show that nests need not be considered simply as united individuals. There can be different reproductive strategies even within the nest. Although, what is still emphasized is Darwin's prime insight that selection works for the benefit of the individual ultimately and not the group.

One of the biggest problems that Darwin had about the fossil record was that it seemed to start abruptly in the Cambrian. Darwin did not have absolute dates, but we know now that this occurred rather more than half a billion years ago. Adding to Darwin's worries, the earliest known organisms were invertebrates like trilobites, and these are extremely sophisticated. Where then were the simple Precambrian organisms that Darwin's theory presupposed? Darwin spent much effort offering ad hoc hypotheses to explain the absence. Today, however, it is not necessary to invent such hypotheses because we have full and detailed knowledge of the fossil record going back nearly four billion years

(Knoll 2003; Knoll and Carroll 1999). Moreover, as expected, the very earliest organisms are very simple, and then, coming up to the Cambrian, they get more complex (Benton 1990, 2009; Raup and Stanley 1978; Sepkoski 2012; Ruse 2006, 2013a).

In addition to speaking to all of this, we have been able to fill in many of the gaps in the later record (Wilford 2006). Some of the most exciting discoveries in the past half century or more have been in that area leading up to *Homo sapiens*. Equaling archaeopteryx and its importance, in the early 1970s, American paleoanthropologist (student of human origins) Don Johansson and his colleagues discovered “Lucy,” *Australopithecus afarensis* (Johansson and Edey 1981). This is a small primate, about four million years old, who lived in East Africa. She is humanlike in that she walked upright, and yet she had a brain the size of the chimpanzee (about 400 cc as opposed to modern humans who have brains about 1200 cc). Some of the most troublesome “missing links” are missing no longer. From being a worry to the Darwinian evolutionist, the fossil record has become one of its greatest sources of comfort.

The coming of continental drift, fueled by the mechanism of plate tectonics, has obviously transformed our understanding of the geographical distributions of organisms (Hallam 1973; Frankel 2017). We can today readily explain why it is that often we find fossils representing the same species in very different parts of the world – for instance, in Africa, India, and Antarctica. It is simply because, at some point in the past, these different landmasses were all joined together and their inhabitants could roam freely across. The lands started to drift apart, and the fossil remains of the earlier inhabitants were separated by vast tracts of ocean.

At the same time, thanks to more sophisticated understandings about how organisms can travel from one area to another, today’s evolutionists can throw considerable light on the relationships between the living organisms on different landmasses. For instance, there has been much successful effort devoted to the relationships between the inhabitants of North America and the inhabitants of South America. It is shown how there was an interchange when the lands were joined and how newcomers succeeded with greater or lesser

success when they traveled into new ecological surroundings. The overall theory is still very Darwinian, but in all details it has been completely transformed.

Systematics underwent a major revolution of its own about 30 years ago (Hull 1988). Thanks to new techniques, brought about in large part by the introduction of computers which were able to digest huge amounts of information, new ways of classifying organisms were devised. “Cladism” is a far more sophisticated way of working out genealogical relationships than anything that existed previously. It is true that some of the early enthusiasts for cladism were less than enthusiastic Darwinians. They were not much interested in adaptation – after all, by the time that the taxonomist gets to work the specimens are usually dead and hence not using their body parts – and so tended to downplay the need of selection. But, with the passage of time, it has become more and more apparent that the classifications of today represent not just evolutionary relationships but evolutionary relationships that were brought about by natural selection.

Some of the most exciting discoveries of all have occurred in morphology, considered in a broad sense. Thanks to molecular biology, we can now compare organisms right down at the most basic levels, far below the physical features known to Darwin and his contemporaries. Truly outstanding has been the way in which molecular biologists have been able to show that there are homologies in the DNA molecule between organisms very far apart, notably between humans and *Drosophila* (fruit flies) (Ruse 2006; Carroll 2005; Carroll et al. 2001). This does not disprove Darwinism. Anything but! What it shows rather is that nature does not build each organism from scratch, as it were. Rather organisms are built on modular principles, rather like Lego toys. We start with a set of different parts: building things one way we get fruit flies and building things another way we get humans. It is entirely analogous to Lego: building things one way we get the White House, and building things another way we get the Statue of Liberty. The important point is that it is selection that guides the process.

Finally, we come to embryology, or as it is known today “evolutionary development” (evo-devo). Again, there are echoes of the Huxley stand on adaptation. We find enthusiasts who suggest that selection is unimportant, merely acting as a garbage collector of failed new forms. Truly, this is far from the case. What today’s developmental biologists are able to show is that often change does not involve new genes making new characteristics as such. Rather, change comes about through adjusting rates of growth (Gould 2002). By stretching an organism or increasing the number of segments, you can often make something very new indeed, without the need of finding whole new body parts. But how it is determined which organisms survive and reproduce, and which do not, is of course a Darwinian matter. Selection monitors organisms in every generation. It never takes a break. In other words, as so often is the case, the new theories and Darwinian selection are complements rather than rivals.

Conclusion

The great Greek philosopher Heraclitus said “you cannot step into the same River twice,” meaning that everything changes. The equally great Greek philosopher Parmenides said “nothing changes.” The fate of Darwinian theory shows that both philosophers were right! Everything has changed since the days of the *Origin of Species*. Nothing has changed since the days of the *Origin of Species*. If Charles Darwin came back to Earth today, he would be delighted.

His Place in Culture

Charles Darwin’s theory of evolution through natural selection was always more than just a scientific theory. From the first, people recognized that it had major implications throughout culture. In this concluding entry, we shall consider some of these implications. Let us start with religion.

American Religion

We have seen that, for all there was some initial objection to the message of the *Origin*, by about 1870 even religious people (with exceptions to be

noted below) had taken Darwinism on board (Roberts 1988; Moore 1979). They had accepted the fact of evolution. Although, as with just about everybody else, there were serious questions about whether or not natural selection was that powerful and effective. One place where Christians generally wanted to make an exception was with respect to humankind. It was not that they were denying that our physical bodies had evolved but rather that when it came to immortal souls, special intervention was deemed necessary. However, given that everybody agreed immortal souls are not scientific notions, this was not terribly troublesome.

One important point where Darwinism did have a significant effect was with respect to natural theology, that part of theology that attempts to get to God through reason rather than through faith (Ruse 2018). Although Darwinism clearly challenges aspects of revealed theology – the part of theology, like belief in the Bible, that does center on faith – it was for most people not a big issue. The Genesis stories had long been considered metaphorical. Natural theology was different. Before Darwin, even skeptics like David Hume admitted that something extra seems to be needed in order to explain the design-like nature of organisms. After Darwin, even if natural selection was not all-powerful, it was realized that we were well on the way to providing natural explanations of the adaptive nature of organic life. This did not lead straight to atheism; however, it was realized that Darwinism was a severe blow against those who argued that the design-like nature of the organic world necessitates a belief in a God. As Thomas Hardy shows in his poem “Hap,” written in 1866 less than a decade after the *Origin*, it was not so much that God was nonexistent but that He was irrelevant, indifferent to our fate.

IF but some vengeful god would call to me
From up the sky, and laugh: “Thou suffering thing,
Know that thy sorrow is my ecstasy,
That thy love’s loss is my hate’s profiting!”

Then would I bear, and clench myself, and die,
Steeled by the sense of ire unmerited;
Half-eased, too, that a Powerfuller than I

Had willed and meted me the tears I shed.

But not so. How arrives it joy lies slain,
And why unblooms the best hope ever sown?
—Crass casualty obstructs the sun and rain,
And dicing time for gladness casts a moan. . . .
These purblind doomsters had as readily strown
Blisses about my pilgrimage as pain.
(Hardy 1994, 5)

One should say that here, as always, the discussion was not going on in vacuum. Many theologians independently of science were already feeling uncomfortable about natural theology. For instance, the great English religious thinker John Henry Newman, who started life as an Anglican but ended as a cardinal in the Church of Rome, always downplayed the importance of natural theology. He felt that the God of the natural theologians – the God of power and omnipotence – was not the God of Christianity, the God of love and compassion (Ruse 2015). So, he for one rather welcomed Darwinism rather than repudiated it. What Newman did not encounter, as he made his move from Canterbury to Rome, was much objection to the idea of evolution as such. By and large, the Catholic Church decided to sit this one out (Appleby 1999). At the end of the nineteenth century, it was much more concerned with the rise of modernism and like issues than with scientific theories. It is true that there was some opposition within the church to evolution, but it was far from universal. So long as evolution was not taken to be denying essential elements of faith, it was left alone.

Thus, things continued and would probably have continued down to this day had not other factors arisen. For a number of reasons, Americans saw the growth in the nineteenth century of a homegrown form of Protestant, evangelical Christianity (Noll 2002). This was a Christianity which was firmly Bible-based and that insisted on reading the creation stories of Genesis in a very literal fashion. There are many reasons for the development of this movement, not the least of which were the quarrels both before and after the Civil War. Particularly in the South, before the war the Bible was taken as justification for slavery. Then, after the defeat in the war, the Bible was used as

justification for the troubled state of the South. Sermon after sermon was preached on the theme that God afflicts those most whom he loves the most and explicit analogies were drawn between the Israelites in captivity in Babylon and the South pressured by outsiders from the North.

Evolution was added to this mix (Numbers 2006). After the war, in the North there was a great drive toward industrialism, education, and science generally. Evolution was taken to be the epitome of the underlying philosophy of progress and was embraced by the general population as well as by their leaders. After the war, in the South there was a longing for a mythical past and determination to slough off changes imposed from outside. Evolution was as important to Southerners as it was to Northerners, but in the South it was taken as a symbol of all that is wrong. It had to be disproved in every possible way.

As is well known, this conflict continued into and through the twentieth century. In 1925 in the state of Tennessee, a young schoolteacher John Thomas Scopes was prosecuted for teaching evolution to his students (Larson 1997). The offense was led by three-time presidential candidate William Jennings Bryan and the defense by the notorious, agnostic lawyer Clarence Darrow. Both sides claimed victory. Scopes was found guilty, but the conviction was overturned on a technicality. The South took the trial as a symbol of defiance. The North took the trial as a symbol of the importance of science and the crudity of thinking in the South. One chilling effect was that, after the Scopes trial, evolution was pretty much banished from textbooks and indeed from any teaching in the schools of the nation. Paradoxically, this happened as much in the North as in the South, because textbook manufacturers tended to produce one uniform edition, dumbed down to the lowest, acceptable level.

Creationism

Biblical literalism, particularly focusing on the absolute truth of the Genesis stories of Creation, revived strongly after the Second World War. Americans were terrified of nuclear conflict with the Russians. Thus, an evangelical religion that focused on cataclysmic events in the past –most

notably Noah's Flood – things taken as premonitions of Armageddon to come, found a ready market. *Genesis Flood*, published in 1961, authored by biblical scholar John C. Whitcomb and hydraulic engineer Henry M. Morris, was a runaway bestseller. Creationism, or as it was sometimes called Scientific Creation, found many adherents, paradoxically just at the time when Darwinian evolution was finally moving forward rapidly as a fully-fledged, professional science.

There were bound to be clashes. In 1981, in the state of Arkansas, a law was passed insisting that schoolchildren be taught Creationism along with evolution (Ruse 1988). Thanks to the US Constitution separating church and state, it was soon found illegal and overturned. However, nothing daunted, like the phoenix literalists rose again from the ashes, and by the 1990s a new version of literalism was being promoted. The so-called Intelligent Design Theory claimed that there are aspects of the organic world that are “irreducibly complex” and thus cannot be explained by natural means (Johnson 1991; Behe 1996; Dembski 1998; Dembski and Ruse 2004). The motor driving the tail, the “flagellum,” on bacteria was one example. One must therefore invoke a designer, and, although the proponents tended to be rather cagey on the subject, there was little doubt that this designer was to be identified with the God of the Bible. Creationism lite, perhaps, but Creationism nevertheless (Pennock 1998; Miller 1999). Again, a court case occurred and again literalism was pushed back (Pennock and Ruse 2008). But it continues to thrive today.

Interestingly, in recent years, evolutionists have gone in parallel directions to the Creationists, inasmuch as they have entered the public domain and started to argue strongly for the imposition of their views against all alternatives. Undoubtedly sparked by the horrors of 9/11, when Moslems flew planes into the World Trade Center and the Pentagon, these fanatics have argued vehemently not just for evolution but against all forms of Christianity and other religions. The so-called New Atheists, among whom one can name the British biologist and popular science writer Richard Dawkins (2006) and the English-born, American-residing,

journalist Christopher Hitchens (2007), argue that all forms of religion are not just false but socially dangerous (Also Harris (2004) and Dennett (2006)).

For better or for worse, just as in the late nineteenth century, evolution was taken as a banner for modernity and right-thinking, so today for the new atheists, evolution has a very similar role (Ruse 2019c). And we find a counter in the Intelligent Design Theorists, who usually cannot wait to move on from the fossil record to condemnations of modern life, including abortion on demand and gay marriage. The paradox is that, although Charles Darwin would almost certainly have agreed with many of the claims made by the new atheists, he would've drawn back with horror from their tactics. Ever the English gentleman, Darwin would have thought that it is socially crude and politically inopportune to attack Christianity in the open way advocated by Dawkins and Hitchens and associates.

This clash over evolution is continuing and no resolution is yet in sight. Up to recently, it was very much an American phenomenon. However, increasingly it is being exported to other countries (Numbers and Stenhouse 1999). For instance, Creationism of various kinds has found receptive ears in several Muslim countries, and there too evolution is taken to be a symbol of all that is wrong. Likewise, in Britain and in Australia, one finds enthusiasts for Creationism and attempts to introduce it into the schools. It is surely paradoxical that, at a time when evolutionary biology has matured into one of the most important areas of natural science, in the public domain, it should be under ever-increasing pressures.

One must add that complexifying the picture is the fact that many Darwinians make somewhat of a secular religion from their science, a sort of evolutionary humanism (Kitcher 2014). Picking up on what was said earlier about the Providential underpinnings of the Christian cause and the Progressivist underpinnings of the Darwinian cause, the latter is used as a basis for supplying all that one finds in conventional religions, especially Christianity – a story of origins, a special exalted place for humankind, moral directives (see more in the next section), and more (Ruse 2005, 2017b,

2018, 2019b). Darwinians are fully entitled to do this if they want – not all do want (having given up the spiritual religion of childhood they are loath to replace it with a secular religion of adulthood) – but it must be realized that this is an additional goad to the religious, especially the evangelical religious, and it is little wonder that there is opposition and bitterness.

Social Darwinism

Closely related to the debates about religion have been debates about the implications of Darwinism for moral and social behavior. As it happens, after the *Origin* Darwin was but a minor player in this movement, and, although later generations labeled the movement “Social Darwinism,” in many respects Darwin stayed on the sidelines (Ruse 2017b). The main proponent of bringing evolutionary thinking into the area of social and moral thinking and behavior was Herbert Spencer. He argued strongly that society should be based on an evolutionary foundation. Notoriously, he abstracted a version of the struggle for existence from the animal and plant world and applied it to the social world. He therefore argued for a rather extreme libertarian or laissez-faire form of society, where government at plays but a little role and individuals and organizations are allowed to battle it out for supremacy (Richards 1987). It is hardly surprising that some of Spencer’s most enthusiastic supporters were American industrialists, notably John D. Rockefeller the first and the steel baron Andrew Carnegie (Ruse 2009). As we have seen, this kind of thinking also found an enthusiastic response in several of the novelists writing around the end of the nineteenth century, notably Jack London and his *The Call of the Wild*.

However, as always – and as we have seen already – things are a little more complex than one might suspect from popular accounts. Not all who brought evolution to bear on social issues were enthusiasts for libertarian ways of behaving. For instance, Alfred Russel Wallace (1900) was always a socialist. He therefore emphasized what he took to be the group effects of natural selection, arguing that state support is in fact biologically justified. Spencer became much more holistic over the years – society as an organism – and

dropped many of the cruder exhortations (Spencer 1879). And then, somewhat off at a tangent, there was the Russian anarchist Prince Peter Kropotkin (1902). He argued that animals naturally evolved a sense of “mutual aid.” This applies also to humans, who would be best off in small societies without heavy government intervention. He thought that given such a social situation, human happiness would be maximized in a way that is not possible otherwise.

Today’s Creationists make much of links that they see between Darwinian theory and the National Socialist movement that swallowed Germany in the 1930s and 1940s (Weikart 2004). They argue that there is a direct line from the *Origin*, with its talk about struggle for existence, to Hitler’s demands for living room for the Germans at the expense of nations to the East. To be fair, something must have caused Hitler and his vile associates, and it would be naive to pretend that nothing in Social Darwinian theorizing (whether or not this was due to Darwin himself) had any effect in this respect. However, there were clearly many other factors leading to the national socialists, and these had at least if not more of an effect (Richards 2013). For a start, there was the volkish movement in Germany coming out of the nineteenth century, something obsessed with the glory in the past (think of all those Wagnerian operas) and looking forward to triumph in the future. Then there were issues to do with religion, and it is certainly not implausible to think that the anti-Semitism of Christianity had at least some effect on Nazi thinking. It is also worth mentioning that although one does sometimes find Hitler parroting Social Darwinian ideas, in many respects the Nazis were deeply opposed to Darwinian thinking (Ruse 2018). For a start, it is of the essence of evolution that all humans are related. Aryans and Jews and others are people of one blood. Nazi theorists realized this, and for this reason one finds that there was often a very distant attitude toward evolution. In short, one should be very wary of simple links between Darwin and the horrible social movements of the twentieth century.

Do we find Social Darwinism alive and well today? Certainly not by that name; however,

undoubtedly, there are those who promote ethical and social ideals in the name of evolution (Ruse 2005, 2019b; Ruse and Richards 2017). One of the best known in America today is Edward O. Wilson (1984, 2002, 2012), whom we met in the last entry as one of the founders of sociobiology. Wilson, who was raised as an evangelical Christian, is ardent in his belief that our evolutionary origins are highly significant, both explaining our ethical inclinations and pointing to the moral tasks that humankind faces today. In particular, he argues strongly that humans have evolved in symbiotic relationship with the rest of nature – a world of plastic would literally be fatal to us all – and he argues therefore that morally we have an obligation to preserve biodiversity. Faithful to his beliefs, in recent years Wilson has been much involved in campaigns to preserve and protect the Brazilian rainforests (Wilson 1992, 1998).

Knowledge

Moral issues are but one side to traditional philosophical inquiry. There is also the question of knowledge (Ruse 1986, 2009). If we are truly modified monkeys rather than modified mud, that is to say if we are truly the end result of evolution through natural selection rather than the creation of a good God miraculously on the sixth day, does this not have immediate and important implications for the ways in which we think and reason? Many today would argue that it does. In fact, this is a line of thought which goes back to Darwin himself, although (as with Social Darwinism) it was more in America that these ideas were picked up.

In the latter part of the nineteenth century and into the twentieth century, one has the so-called “Pragmatist” movement – Charles Sanders Peirce (1997), William James (1904), and then somewhat later John Dewey. They all acknowledged a great debt to Darwin. If the Darwinian process is one of putting up new variations and then subjecting them to the fire of the struggle for existence, then is not knowledge acquisition something very similar? One comes up with new ideas and puts them into the general discourse and then sees how they fare. Good ideas succeed, bad ideas fade from sight. It is not a matter of ultimate truth or falsity but much more a very pragmatic matter. What works? The

Pragmatists argued that if something is successful for a while, then that is the best we can hope for. It is all very Darwinian (Wiener 1949). There is no absolute truth, no trees falling in the forest and making a sound when no one is around.

There are still many who would argue this way today. However, increasingly as our knowledge of the human brain is developed and refined, more and more people take a slightly different tack. They argue strongly that the ways in which we think and reason are a reflection of adaptive strategies that proved successful in our past. Even scientific reasoning, it is argued, has its justification in evolution (Cosmides 1989). Why should we take something like a consilience of inductions to be a good form of reasoning? Simply because those protohumans who thought in consilient ways tended to survive and reproduce and those that did not. Those humans who took full account all the clues and reasoned (let us say) that they point to an unseen-but-hovering predator stood a better chance of living until tomorrow than those who simply ignored the clues. They may have been happy in their ignorance. One hopes so, because their lives would tend to be short.

Conclusion

As with religion, debates about ethics and knowledge are ongoing. There are those who are enthusiastic Darwinians. There are those who are not (Plantinga 1991; Nagel 2012; Fodor and Piattelli-Palmarini 2010). But for or against, no one denies that Darwin’s ideas stimulate and provoke. For that reason if for no other, no educated person today should be ignorant of the life and labors of Charles Darwin. In science and in culture, he is one of the seminal figures of all time. I hope I have shown you also that his ideas are not just important. They are incredibly interesting.

Charles Darwin: Theory of Natural Selection

David Stack
University of Reading, Reading, UK

Synonyms

[Survival of the fittest](#)

Definition

Natural selection was the term Darwin used to describe the evolutionary process by which favorable or advantageous traits and characteristics are preserved and unfavorable or disadvantageous ones discarded.

Introduction

Natural selection was the term Charles Darwin (1809–1882) used for the main mechanism by which he understood evolution to work. Natural selection was first announced publicly in a joint reading of his and Alfred Russel Wallace's papers at the Linnean Society in July 1858 (Darwin and Wallace 1858) and first developed in published form in Darwin's most important book, *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* (1859). As the full title of the Origin indicates, natural selection was key to Darwin's evolutionary argument, and the fourth chapter of the Origin was devoted to an exposition

of its operation. Darwin's definition of natural selection was deceptively simple: "This preservation of favourable variations and the rejection of injurious variations, I call Natural Selection" (Darwin 1859). Packed within the term, however, were a series of assumptions and implications which Darwin had taken over 20 years to work through and which critics of his thought subsequently sought to pull apart.

At its simplest, natural selection describes a process in which favorable or advantageous characteristics – physical or psychological – are preserved and unfavorable or disadvantageous characteristics are discarded. This is a "natural" process because it is said to occur without the conscious intervention of either the organism which is undergoing change or any external selector. The process of "selection" is in fact one of the preservation and discarding, determined by the utility or disutility of any given characteristic. What is useful is "selected," in the sense that it is preserved and strengthened across generations; what is useless is weakened and eventually discarded across generations. Natural selection, therefore, requires an extended time-scale and, like all evolutionary theories, depends upon inheritance.

Darwin's theory of evolution by natural selection is premised upon two prior conditions, a naturally occurring variation within species and an ongoing "struggle for life" among all organisms, in which the fittest survive and the weakest are eliminated. Natural selection occurs only as a result of variation and the "struggle for life" but is not synonymous with them. As Darwin explained in the *Origin*:

If during the long course of ages and under varying conditions of life, organic beings vary at all in the several parts of their organisation, and I think this cannot be disputed; if there be, owing to the high geometrical powers of increase of each species, at some age, season, or year, a severe struggle for life, and this certainly cannot be disputed; then, considering the infinite complexity of the relations of all organic beings to each other and to their conditions of existence, causing an infinite diversity in structure, constitution, and habits, to be advantageous to them, I think it would be a most extraordinary fact if no variation ever had occurred useful to each being's own welfare, in the same way as so many

variations have occurred useful to man. But if variations useful to any organic being do occur, assuredly individuals thus characterised will have the best chance of being preserved in the struggle for life; and from the strong principle of inheritance they will tend to produce offspring similarly characterised. This principle of preservation, I have called, for the sake of brevity, Natural Selection. (Darwin 1859)

This process of natural selection is the core of Darwinism and constitutes the essence of Darwin's distinct contribution to science.

The Origin of Natural Selection

Darwin developed his understanding of natural selection even before he began to use that specific term. Although Darwin first developed a distinctive understanding of evolution in the late 1830s, it was not until the early 1850s that he came to regularly and confidently refer to his theory as "natural selection." So enamored of the term did he then become that after he began work on his never-to-be-completed "big species book" in 1856, he decided that it would be entitled *Natural Selection* (Stauffer 1975).

In his first unpublished "Sketch" of his species theory, however, written in 1842, the term "natural selection" appears only twice – once as a subheading and once in the main body of the text – in over 15,000 words. Despite the "Sketch" covering, in outline, much of the same subject matter that Darwin would later tackle in the *Origin*. The term is only slightly more prominent in Darwin's also unpublished 1844 "Essay": appearing 6 times in the 60,000 words that again anticipate the structure and argument of the *Origin* (Darwin 1909). One of the few aspects of the *Origin* that is not anticipated in these earlier renderings of Darwin's theory was the separate consideration of natural selection that formed the fourth chapter of his book.

The relative absence of the term, and the fact that neither the "Sketch" nor the "Essay" did Darwin trouble himself to introduce or explain the term, does not diminish the centrality of the underlying idea to both texts and the strong connecting thread between these two manuscripts and the *Origin*. Nonetheless, the fact that Darwin used the term

only sparingly in the early 1840s, compared with well over 200 times in the *Origin* is striking. What seems to have changed is that Darwin had become accustomed to the term during his studies of domestic breeding. After Darwin's publisher John Murray complained, upon receipt of the manuscript of the *Origin*, about the obscurity of the term "natural selection," Darwin wrote to the geologist Charles Lyell expressing some surprise. "Why I like the term," he told Lyell, "is that it is constantly used in all works on breeding, and I am surprised that it is not familiar to Murray: but I have so long studied such works that I have ceased to be a competent judge" (<http://www.darwinproject.ac.uk/DCP-LETT-2439>).

This remark is doubly illuminating: it confirms Darwin's derivation of the term and that his use of it grew out of his immersion in the world of animal breeders. This is significant because breeders used the term "natural selection" as convenient phrase to contrast unknown causes of changes in species with the deliberate changes which they actively sought to engineer. This contrast, and subsequently the analogy, between "natural selection" (changes that arose without any deliberate action or design on the part of the breeder) and "artificial selection" (changes that were actively sought, instigated, and accentuated by breeders) was integral to Darwin's understanding.

Modern readers of the *Origin of Species* are sometimes perplexed or amused by the first chapter, "Variation under Domestication," dwelling so long upon the subject of pigeon breeding, but in this chapter Darwin is both laying the foundations for an analogical argument and providing an insight into the development of his thought. Having established the principle of modification and selection in breeding, Darwin proceeds, in Chapters 2 and 3, to consider first the variability of species in the state of nature and then the ubiquity of a struggle for existence, before, in his fourth chapter, explaining how "it follows that any being, if it vary however slightly in any manner profitable to itself, under the complex and sometimes varying conditions of life, will have a better chance of surviving, and thus be naturally selected" (Darwin 1859).

In case any reader had missed, or doubted, the analogy, Darwin restated it clearly:

I have called this principle, by which each slight variation, if useful, is preserved, by the term of Natural Selection, in order to mark its relation to man's power of selection. We have seen that man by selection can certainly produce great results, and can adapt organic beings to his own uses, through the accumulation of slight but useful variations, given to him by the hand of Nature. But Natural Selection, as we shall hereafter see, is a power incessantly ready for action, and is as immeasurably superior to man's feeble efforts, as the works of Nature are to those of Art. (Darwin 1859)

In his *The Variation of Animals and Plants under Domestication* (1868) – the only part of his unfinished "big book" to be published in his lifetime – Darwin went further, distinguishing three types of selection: methodical selection, which arose from breeders systematically endeavoring to modify a breed; unconscious selection, "which follows from men naturally preserving the most valued and destroying the less valued individuals, without any thought of altering the breed;" and natural selection, "which implies that the individuals which are best fitted for the complex, and in the course of ages changing conditions to which they are exposed, generally survive and procreate their kind." Unconscious selection, Darwin noted, graduated into methodical selection and could rarely be distinctly separated, while natural selection was sufficiently strong to come, "to a certain extent into action, independently of, and even in opposition to, the will of man" (Darwin 1868).

The Strength of Natural Selection

Darwin's certainty of the strength of natural selection was rooted in his understanding of the forces underlying its operation. As already noted, natural selection was premised on two prior processes: naturally occurring *variations* and an intense *struggle for life*. In order for natural selection to make sense, that is, one needed to accept (i.) the mutability of life forms and (ii.) the universal prevalence of a competition for the means of survival. Neither idea was new: Darwin's

innovation was to bring them together as the foundation of his own, innovatory evolutionary mechanism – natural selection.

Darwin's notebooks show that by 1837 he was deeply immersed in the problem of the mutability of species and was trying to understand how the process of the transmutation of species might operate (Gruber 1974). At this point his growing conviction that evolution occurred was matched by a suspicion of the inadequacy of all previous attempts to understand transmutation (see Stott 2012).

His breakthrough came in autumn 1838, Darwin later recalled, when he read Thomas Malthus's *An Essay on the Principle of Population* (1803), "for amusement." Malthus's *Essay* argued that humans had an inherent tendency toward overpopulation, as they reproduced faster than the food supply could be increased, inducing regular struggles for subsistence. It was an argument Darwin encountered with a sense of recognition:

and being well prepared to appreciate the struggle for existence which everywhere goes on, from long-continued observation of the habits of animals and plants, it at once struck me that under these circumstances favourable variations would tend to be preserved, and unfavourable new ones to be destroyed. The result of this would be the formation of a new species. Here, then, I had at last got a theory by which to work ... (Barlow 1958)

Reading Malthus was not merely the midwife to the birth of Darwin's theory of natural selection; the Malthusian struggle was a key constitutive element in his understanding of its operation. Only if there was a "Struggle for Existence amongst all organic beings throughout the world, which inevitably follows from their high geometrical powers of increase," would Darwin be able to explain why some traits and characteristics were favored, and others eliminated, and this struggle, he told readers of the *Origin*, was "the doctrine of Malthus, applied to the whole animal and vegetable kingdoms" (Darwin 1859).

By making overpopulation key to the operation of natural selection, Darwin's theory of evolution was distinguished from that of his predecessors in several important respects. In particular, natural

selection made competition, utility, and extinction central evolutionary themes.

Prior to Darwin, the most fully developed theory of evolution was to be found in the writings of the French zoologist Jean-Baptiste Lamarck (1744–1829). Lamarck argued that the transmutation of species occurred by a process of inheritance of acquired characteristics and that new characteristics were acquired by species through the use and disuse of organs, leading structures to either develop or disappear. The prompt for the increased or decreased use of any particular organ was, in turn, an internal urge, rooted in an innate tendency to develop in a certain way. Lamarck's understanding, that is, was orthogenetic, with organisms developing toward a predetermined goal.

Evolution by natural selection, by contrast, occurred because certain variations proved advantageous or disadvantageous in the ongoing struggle for life. This made natural selection directionless. The key to which variations prospered or failed was their *utility* in the ongoing *competition* for scarce resources. There was no orthogenetic element to this, as there was no predetermined direction to natural selection, beyond whatever proved most useful. Natural selection was, in contrast to Lamarck's understanding, a brutal and destructive mechanism, which worked by the constant overproduction of organisms, and the recurrent elimination of those less fitted for the struggle for life. So brutal was this process, Darwin asserted, that *extinction* – which Lamarck's account had precluded – was a frequent occurrence under natural selection. Indeed, "extinction and natural selection," Darwin declared, "go hand in hand" (Darwin 1859).

Darwin's rooting of his theory of natural selection so firmly in the Malthusian population principle had two contradictory consequences for the reception of his ideas. On the one hand, notions of competition, struggle, and utility were so familiar, especially as adumbrated through the new social science of political economy, that natural selection would have echoed with an almost common sensical familiarity for many readers. On the other hand, however, it immediately threw up many of the same theological problems – not least why

would an omnipotent and benevolent deity depend upon a mechanism that entailed death, destruction, and apparent evil? – that had greeted Malthus’s theory (see Pullen 1987).

Darwin neatly sidestepped this in the *Origin*, arguing that there was “grandeur” in the view of life which saw “from the war of nature, from famine and death, the most exalted object which we are capable of conceiving, namely, the production of the higher animals, directly follows” (Darwin 1859). This type of language, self-consciously deployed to give comfort to those with religious sensibilities, could not entirely soften the blow that Darwin had delivered. Taken to its logical conclusion, natural selection meant an end to teleology, an end to special interventions, an end to all notions of design, and an end to the natural theology associated the name of William Paley. Writing, toward the end of his life, in his “Recollections,” Darwin was clear:

The old argument of design in nature, as given by Paley, which formerly seemed to me so conclusive, fails, now that the law of natural selection has been discovered. We can no longer argue that, for instance, the beautiful hinge of a bivalve shell must have been made by an intelligent being, like the hinge of a door by man. There seems to be no more design in the variability of organic beings & in the action of natural selection, than in the course which the wind blows. Everything in nature is the result of fixed laws. (Barlow 1958)

Difficulties with the Term

Although Darwin himself had become increasingly enamored of the term “natural selection” prior to the publication of the *Origin*, his confidence in its appositeness received a blow from the initial reaction of his readers. Writing to Lyell in September 1860, a mere 10 months after the *Origin* was published, Darwin declared: “if I had to commence de novo I would have used natural preservation” (<http://www.darwinproject.ac.uk/DCP-LETT-2931>). The problem, he complained, was that too many readers seemed incapable of understanding the term.

In the third edition of the *Origin*, published in 1861, Darwin inserted an extra paragraph at the start of Chapter 4, to address those writers who

had “misapprehended or objected to the term Natural Selection.” In particular, he sought to correct those who understood natural selection to imply the need for active selection, either by the organism itself or by an external chooser. Part of the misunderstanding, Darwin acknowledged, arose from an ambiguity inherent to the term. “In the literal sense of the word,” he wrote, “natural selection is a misnomer,” which had allowed some readers to suppose that he understood nature to be personified into a “selector” and that natural selection itself was “an active power or Deity.” This, Darwin complained impatiently, was wrong: natural selection was no more an active power or deity than was gravity. When he referred to “nature” he meant only the aggregate action and product of natural laws. The problem, he concluded, was that his readers were failing to understand that “natural selection” was a metaphor “With a little familiarity,” Darwin concluded, “such superficial objections will be forgotten” (Darwin 1861).

This proved to be a rather optimistic assessment. Five years later, in July 1866, Wallace wrote to Darwin to say that he has been “so repeatedly struck by the utter inability of numbers of intelligent persons to see clearly or at all, the self acting & necessary effects of Nat[ural] Selection” and that he was forced to conclude “that the term itself” and Darwin’s illustrations of it were at fault. By comparing natural selection to artificial selection, and by personifying nature as “selecting” and “preferring,” said Wallace, Darwin had deployed a metaphor which, instead of aiding understanding, was proving to be a “stumbling block” (<http://www.darwinproject.ac.uk/DCP-LETT-5145>).

Wallace’s criticisms were well made. In basing natural selection upon an analogy with artificial selection, Darwin encouraged an anthropomorphic conception of selection in which the “power” which “acted” could be seen as an active deity. This was not Darwin’s intention. At the time he wrote the *Origin*, Darwin was, on his own account, still a theist. The agnosticism (and arguably atheism) of his later years was still some way off, but he did not entertain any notion of an active, interventionist god. For Darwin, nature

was a set of fixed laws, and natural selection was directionless beyond favoring whatever was best adapted. Yet his words frequently suggested something else. Thus when he wrote to the US botanist Asa Gray, announcing his new theory, he claimed: “I think it can be shown that there is such an unerring power at work in Natural Selection (the title of my book), which selects exclusively for the good of each organic being” (<http://www.darwinproject.ac.uk/DCP-LETT-2136>). Following this introduction to the concept, it is perhaps unsurprising that Gray became the principal champion among those who sought to reconcile natural selection and natural theology.

Wallace suggested a way out of such misunderstanding. Darwin, he advised, should abandon the term “natural selection” and replace it with the phrase “survival of the fittest.”

This latter phrase, which many now associate with Darwin, had been coined 2 years earlier as a synonym for “natural selection” by Herbert Spencer, in an installment of his *The Principles of Biology* (Spencer 1864). Wallace argued that Spencer’s term was “the plain expression of the facts” – nature did not “so much select special variations, as exterminate the most unfavourable ones” – and, as such, was less liable being “misrepresented & misunderstood” than Darwin’s metaphorical, “and to a certain degree indirect & incorrect,” natural selection.

Wallace’s letter had a limited effect. Darwin did agree to integrate Spencer’s phrase into his work. It was too late to make changes to the fourth edition of the *Origin*, which was already with the publisher, but Darwin used “survival of the fittest” 6 times in the *Variation* and 16 times in the fifth edition of the *Origin* (1869). Nor were these unimportant or incidental uses. Darwin even reworked the title of Chapter 4 of the *Origin* into “Natural Selection, Or The Survival of the Fittest” and in the text described “survival of the fittest” as “more accurate” than and “sometimes equally convenient” with natural selection.

Ultimately, however, Darwin was unwilling to give up his own term. In part this was a matter of practicality: the *Origin* had enjoyed such a wide circulation, and natural selection had “been so largely used abroad & at home,” (<http://www.darwinproject.ac.uk/DCP-LETT-5145>) that Darwin doubted whether its use could be eliminated, even if he had wanted that. And there is no evidence that he did, quite the contrary. Darwin continued to cling to the hope he had expressed to Lyell that in time his readers would come to understand his phrase. This had nothing to do with the obvious criticism that might be made of the term “survival of the fittest,” i.e., it is a tautology with little explanatory value. Rather, Darwin preferred the term “natural selection” precisely for the reason that Wallace questioned its use: it was a metaphor.

A number of scholars, principally Robert M. Young (1971), have made the case that the phrase “natural selection” had an important explanatory role both in the development of Darwin’s thought and in his efforts to persuade others to accept his theory. In the absence of any precise understanding of how inheritance worked, Darwin’s task in the *Origin* was not so much to show evolution in action, or to provide a complete example of the stages by which it occurred, but to stress the greater plausibility of his theory over all other explanations, principally Lamarckism and all notions of special creation. In those circumstances, language mattered: natural selection was more than just a phrase, convenient for summarizing a complex process. For Darwin, “natural selection” was a “theory-constitutive metaphor” (a metaphor which suggests future research strategies) and an “emphatic metaphor,” i.e., one which is bound up with the cognitive content of the theory it seeks to explain (Al-Zahrani 2007).

Difficulties with the Theory

Prior to Publication of the *Origin*

What troubled Darwin most when developing his theory was the need to square natural selection with some apparently awkward scientific facts. The need to work through possible objections, and reconcile his theory to the existing state of scientific knowledge, accounts, in part at least, for the otherwise extraordinary “delay” (van Wyhe 2007) between Darwin’s revelatory reading of

Malthus and the publication of the *Origin* some 21 years later. As a result of the time he took, one feature of the *Origin*, which helped to make it such a compelling argument, was that Darwin led his readers through his own initial doubts and their subsequent resolution. Thus the four middle chapters of the *Origin* are concerned with exploring and resolving various objections and difficulties, including the problems of hybrids, the imperfection of the fossil record, and the problem of producing complex outcomes by a series of insensibly fine gradations.

The “most serious special difficulty” posed to Darwin’s own acceptance of the sufficiency of natural selection, however, came in the form of neuter insects, especially sterile females such as worker ants:

with the working ant we have an insect differing greatly from its parents, yet absolutely sterile; so that it could never have transmitted successively acquired modifications of structure or instinct to its progeny. It may well be asked how is it possible to reconcile this case with the theory of natural selection? (Darwin 1859)

Part of Darwin’s answer to his own question was to emphasize that natural selection applied to “the family” as well as “the individual” and that in the case of social insects, such as ants, it was entirely possible for fertile parents to transmit to their fertile offspring a tendency to produce sterile offspring, if that was beneficial to the community. Natural selection, that is, acted upon fertile parents to regularly produce neuter offspring.

The “climax of the difficulty,” however, as Darwin saw it, was not merely that neuters were produced but that the neuter ants themselves were specialized into two or three “different castes.” Among *Eciton* ants, for example, the neuters were divided into worker and soldier ants, “with jaws and instincts extraordinarily different.” To explain this by natural selection required Darwin to suppose that a graduated series had first been formed, “and then the extreme forms, from being the most useful to the community, having been produced in greater and greater numbers through the natural selection of the parents which generated them; until none with an intermediate structure were produced” (Darwin 1859).

It is obvious when reading the *Origin* that Darwin’s success in resolving this problem, with which he had wrestled for a considerable period, boosted his confidence in natural selection considerably. The fact that natural selection could explain the existence of neuter insects proved, for Darwin, the superiority of natural selection over Lamarckism: “For no amount of exercise, or habit, or volition, in the utterly sterile members of a community could possibly have affected the structure or instincts of the fertile members, which alone leave descendants.” Even in relation to instincts, he argued, there was in nature “one general law, leading to the advancement of all organic beings, namely, multiply, vary, let the strongest live and the weakest die” (Darwin 1859).

Subsequent to Publication of the *Origin*

Although Darwin had satisfied his own doubts about natural selection prior to the publication of the *Origin*, problems remained. There were three principal scientific barriers to winning full acceptance for natural selection, each of which related to the question of inheritance.

First, as compelling as Darwin’s argument was, what the *Origin* offered was natural selection as a *hypothesis* for how evolution worked. The “preservation” of a trait and characteristic occurred by its transmission between generations, with each successive generation accentuating whatever advantage it offered. But, writing before modern genetics, Darwin was not able to explain precisely *how* inheritance worked. In the *Origin* he rather fudged the issue, by making natural selection refer to both the evolutionary *effect* (the favored trait or characteristic) and the *mechanism* (preservation in struggle and hereditary transmission).

In the *Variation*, however, Darwin did attempt to flesh out what he called a “provisional hypothesis” of heredity, which he called pangenesis. Pangenesis brought together an ancient tradition stretching back to Hippocrates with some of the latest thinking in cell theory, in an unconvincing amalgam. According to the pangenesis theory, all parts of the body produced tiny particles (gemmules) which circulated in the blood, but migrated to the gonads, and were passed on to

offspring, before developing as the offspring matured. Because these gemmules were continually produced, it was possible for both somatic and behavioral traits to be inherited (Darwin 1868).

Unfortunately, Darwin's attempt to shore up his theory of natural selection with pangenesis tended to weaken his own theory by opening up space for the very Lamarckian interpretation he had set out to counter. Pangenesis suggested that alterations to body parts would, in turn, alter gemmules and, therefore, that an inheritance of acquired characteristics would be possible.

From our perspective it is easy to see what was missing from Darwin's hypothesis: he lacked a particulate theory of heredity, a distinction between somatic and germ cells, and a concept of dominance, i.e., he lacked modern genetics and molecular biology. It was to take the rediscovery of Mendel's laws of inheritance in the early twentieth century, and their integration with evolutionary theory, to firmly establish the *mechanism* of natural selection. Ronald Fisher's *The Genetical Theory of Natural Selection* (1930) and Theodosius Dobzhansky's *Genetics and the Origin of Species* (1937) were particularly important in this movement, which became known as the "modern synthesis," and gave us natural selection as it is now understood.

The second principal challenge natural selection faced was how to explain the preservation of favorable variations when inheritance was widely believed to involve "blending." The engineer Fleeming Jenkin (1833–1885) became a trenchant and troubling critic of Darwin on this point, arguing in an 1867 review of the *Origin* that any advantageous mutations would be swamped and diluted out of existence within a few generations. Certainly no change could survive across the hundreds or thousands of generations that would be required to bring about Darwin's process of evolution by natural selection (Jenkin 1867). As with inheritance more broadly, this problem would eventually be overcome by the integration of Mendel's theory of particulate inheritance, but Darwin's initial reaction was a concern and a hurried attempt to give a partial answer in the fifth edition of the *Origin*.

What gave Jenkin's criticism added bite was that it chimed with the third challenge to Darwin's theory of natural selection: doubts about the age of the earth.

As Jenkin noted, a process of incremental change required preservation across a huge span of generations, but in the years immediately following publication of the *Origin*, the depth of geological time necessary for natural selection was called into question. William Thomson (later Lord Kelvin) argued that the crust of the earth had solidified no more than 100 million years ago. Darwin was "rattled" by this claim, lamenting Thomson's work as "an odious spectre" and identifying it as "one of my sorest troubles" (Browne 2002). In response, the fifth and sixth editions of the *Origin* placed an increased emphasis on use and disuse explanations of evolution, alongside natural selection, as a means of accelerating aspects of the evolutionary process (Darwin 1872).

Natural Selection and Other Evolutionary Mechanisms in Darwin

This "speeding up" was possible because Darwin had always left room for other factors working alongside natural selection. As he reminded readers of the introduction to the 1874 edition of his *Descent of Man*:

even in the first edition of the 'Origin of Species,' I distinctly stated that great weight must be attributed to the inherited effects of use and disuse, with respect both to the body and mind. I also attributed some amount of modification to the direct and prolonged action of changed conditions of life. Some allowance, too, must be made for occasional reversions of structure; nor must we forget what I have called "correlated" growth, meaning, thereby, that various parts of the organisation are in some unknown manner so connected, that when one part varies, so do others; and if variations in the one are accumulated by selection, other parts will be modified. Again, it has been said by several critics, that when I found that many details of structure in man could not be explained through natural selection, I invented sexual selection; I gave, however, a tolerably clear sketch of this principle in the first edition of the 'Origin of Species,' and I there stated that it was applicable to man. This subject of sexual

selection has been treated at full length in the present work, simply because an opportunity was here first afforded me. (Darwin 1874)

Darwin's defense here was a little disingenuous. With the publication of *The Descent*, in particular, a significant change had occurred in his thought.

In the first edition of the *Origin*, the overwhelming emphasis on natural selection was supplemented by a small section in the fourth chapter, which considered "Sexual Selection," and a brief discussion in Chapter 5 of the evolutionary effects of use and disuse. In both cases Darwin found these other mechanisms to be subsidiary and supplementary to the overriding importance of natural selection. Sexual selection, which Darwin defined as "a struggle between the males for possession of the females," was, he said, "less rigorous than natural selection" and, for the most part, merely reinforced its more powerful counterpart: "Generally, the most vigorous males, those which are best fitted for their places in nature, will leave most progeny" (Darwin 1859). It was the same with use and disuse. Darwin allowed that changed habits could produce an inherited effect and speculated that moles and cave-dwelling fish, for example, may have lost their sight this way, but Darwin also implied that natural selection was the underlying cause of every change and that use and disuse contributed only by accelerating a process that natural selection might have effected, albeit more slowly, on its own.

When Darwin turned to the question of human evolution, however, in *The Descent of Man, and Selection in Relation to Sex* (1871), he identified sexual selection as, in some instances, more powerful than an independent of natural selection.

Natural Selection and Human Evolution

Darwin had not addressed human evolution directly in the *Origin*, limiting himself to the gnomonic prediction: "Light will be thrown on the origin of man and his history" (Darwin 1859).

This deliberate omission certainly helped Darwin finish his book and probably helped to minimize the controversy that the *Origin* provoked. It also, however, meant that by the time Darwin was ready to publish his thoughts, others had already begun the process of applying his theory to human evolution.

Two ideas, in particular, had taken hold in the 12 years that elapsed between the *Origin* and the *Descent*. The first was Wallace's argument, outlined in his 1864 paper *The Origin of Human Races and the Antiquity of Man Deduced From the Theory of "Natural Selection"*, that the human brain effectively removed humans from the bodily effects of natural selection and that natural selection now operated exclusively on the human mind and intelligence. The second, promulgated most prominently by Darwin's half cousin Francis Galton, was that the trappings of civilization seriously impeded or completely prevented the operation of natural selection – physically *and* mentally – and that, in consequence, human evolution was threatened with a reverse process of degeneration (Galton 1869).

Darwin acknowledged this fear in a section of the fifth chapter of the *Descent*, entitled "Natural Selection as Affecting Civilised Nations." "We civilised men," he began, "do our utmost to check the process of elimination; we build asylums for the imbecile, the maimed, and the sick; we institute poor-laws; and our medical men exert their utmost skill to save the life of every one to the last moment." As a result, those who would have been eliminated by the free operation of natural selection were allowed to breed, and "this must be injurious to the race of man" (Darwin 1871). Despite this doom-laden language, which foreshadows the arguments of the later eugenics movement, Darwin's overall conclusion was positive. Whatever impediments society might erect to its operation, Darwin argued, much as he had in the *Variation*, that natural selection was always sufficiently strong to act "independently of, and even in opposition to, the will of man" (Stack 2012).

When explaining physical differences between different human groups, however, rather than

reasserting the primacy of natural selection, Darwin turned to sexual selection. “For my own part,” he wrote, “I conclude that of all the causes which have led to the differences in external appearance between the races of man, and to a certain extent between man and the lower animals, sexual selection has been by far the most efficient.” Darwin still thought that natural selection played the primary role in accounting for the development of man’s “intellectual and moral or social faculties” but doubted its ability to explain racial divergence. Natural selection, Darwin noted, depended upon utility, but “as far as we are enabled to judge (although always liable to error on this head) not one of the external differences between the races of man are of any direct or special service to him” (Darwin 1871). If racial differences were predominantly ornamental or aesthetic, Darwin concluded, they could be better explained by sexual selection.

Human groups, tribes, or races, Darwin suggested, had become their own selectors, breeding themselves to their own ideal:

We have seen that with the lowest savages the people of each tribe admire their own characteristic qualities,—the shape of the head and face, the squareness of the cheek-bones, the prominence or depression of the nose, the colour of the skin, the length of the hair on the head, the absence of hair on the face and body, or the presence of a great beard, and so forth. Hence these and other such points could hardly fail to have been slowly and gradually exaggerated from the more powerful and able men in each tribe, who would succeed in rearing the largest number of offspring, having selected during many generations as their wives the most strongly characterised and therefore most attractive women. (Darwin 1871)

It was a similar story when Darwin came to explain differences in the mental powers of the sexes. “With respect to differences of this nature,” Darwin wrote, “it is probable that sexual selection has played a very important part.” Again Darwin did not entirely discount natural selection: male intellect, he argued, had been honed both in the competition of natural selection (from which females had been relatively sheltered) and sexual selection, the struggle “for the possession of the females” (Darwin 1871).

The result, when supplemented with Darwin’s use and disuse argument that it was the age at which a characteristic was strengthened which determined when it would be transmitted (thus males inherited distinctively male, and females distinctively female, characteristics), was that Darwin’s mix of natural selection, sexual selection, and use and disuse explanations combined to produce an evolutionary basis for male “superiority.”

Male genius, Darwin maintained, had:

been developed in man, partly through sexual selection,— that is, through the contest of rival males, and partly through natural selection, — that is, from success in the general struggle for life; and as in both cases the struggle will have been during maturity, the characters thus gained will have been transmitted more fully to the male than to the female offspring. Thus man has ultimately become superior to woman. (Darwin 1871)

Here we can see that Darwin’s dilution of natural selection as the main mechanism for human evolution went hand in hand with arguments that gave a naturalistic basis to the social inequalities of the late Victorian world and tended to justify racial and sexual inequality (Goodman 2019). This may not have been his conscious intention, but it is striking that the normally cautious Darwin offered firm conclusions despite the fact that, by his own admission, his views “on the part sexual selection has played in the history, want scientific precision” (Darwin 1871).

A useful contrast can be made here with Wallace, an advocate of equality, who despite his misgivings about the term remained steadfast in his commitment to natural selection, to the exclusion of all other evolutionary mechanisms. In his rendering of their shared discovery, *Darwinism: an exposition of the theory of natural selection, with some of its applications* (1889), Wallace argued for the “overwhelming importance of natural selection over all other agencies” and rejected Darwin’s account of sexual selection. Indeed so unrelenting was he in his advocacy of a “pure Darwinism” that George J. Romanes characterized Wallace as a “neo-Darwinian” for “seeking to out-Darwin Darwin by assigning an exclusive

prerogative to natural selection” (Romanes 1895). This was never Darwin’s position.

Summary

Natural selection was the term Darwin used to describe both the mechanism and the effect of the evolutionary process by which favorable or advantageous traits and characteristics are preserved and unfavorable or disadvantageous ones discarded. The “selection” process is “natural” in the sense that it occurs without any conscious intervention (there is no “selector”) in response to an ongoing “struggle for life.” Traits and characteristics favorable to survival in that struggle are preserved and developed. This, for Darwin, is the basis of evolution. Key to the process is inheritance, but, as he was writing without knowledge of modern genetics, Darwin’s presentation of natural selection did not include any detailed understanding of how inheritance worked.

Although Darwin succeeded in winning acceptance for the general notion of evolution, the mechanism of natural selection remained controversial. Partly this was due to a lack of direct evidence. Besides the absence of any precise understanding of genetic inheritance, Darwin struggled against gaps in the fossil record, the elusiveness of transitional forms, and his inability to demonstrate direct instances of natural selection in operation.

His major work, *On the Origin of Species by Means of Natural Selection*, presented “one long argument” in favor of his mechanism, but critics pointed out that swamping, blending, dilution, and the uselessness of incipient structures would all tend against the process he described. A further challenge came from William Thomson’s work on the cooling of the earth, which suggested that the planet was too young to have witnessed the magnitude of species development, wrought by incremental change, which Darwin suggested. Other readers misunderstood what Darwin meant by natural selection and supposed an active selector to be at work. This led some of Darwin’s allies,

most notably Wallace, to suggest abandoning the term.

Darwin refused and continued to favor “natural selection” as a metaphor. Nonetheless, in his later works, and even in later editions of the *Origin*, Darwin was keen to stress that, although the most powerful, natural selection was not the only mechanism by which the evolutionary process occurred. Especially in the case of humans, discussed by Darwin in *The Descent of Man*, use and disuse and sexual selection were given greater prominence. One consequence of this was that although an acceptance of evolution flourished in the late nineteenth century, an understanding and acceptance of Darwin’s mechanism of natural selection were less widespread.

The success and prevalence of natural selection that we know today have its roots in the “modern synthesis” of the early twentieth century, which united Darwin’s hypothesis of natural selection with the understanding of genetics that he lacked.

Definition

Sexual selection is the form of selection that operates specifically on the reproductive success of individuals. Natural selection is associated with the struggle for survival (which includes reproduction), but sexual selection is entirely associated with an organism's ability to find a mate, successfully copulate, and produce offspring.

Introduction

Darwin's theory of evolution by natural selection is essential and is adequate to explain the diversity of life on this planet. The theory – based on genetic variation, adaptation, and inheritance – is all encompassing, and as the great evolutionary geneticist Theodosius Dobzhansky remarked, “nothing in biology makes sense except in the light of evolution.” Evolution is the string theory of biology. As a grand theory, its descriptors include genetic variation, selection, adaptation, speciation, and extinction. Since the theory applies to all organisms, the details of the organisms do not matter to the explanatory power of the theory. Fitness can be defined in terms of genes, not organisms, as it has been done in population genetics. However, if we want to understand how

organisms interact and adapt to their environment and how they live, mate, reproduce, and die, we need to look at organisms at the scale of their life, which varies from days to months and years. It is at this scale that the theory of sexual selection, along with natural selection, becomes essential.

To understand sexual selection, it is important to understand the context in which Darwin felt the need to propose this theory in a separate book *The descent of man and selection in relation to sex* (Darwin 1871), after publishing his book on the theory of natural selection (Darwin 1859). It is also important to understand how sexual selection is related to and yet is fundamentally different from natural selection. Hunger and sex are the two driving forces of evolution; organisms need to eat to survive and to reproduce in order to perpetuate themselves. Darwin's theory of natural selection included competition for food and sex as well as surviving challenges arising directly from the environment. Sexual selection centers more on sex and reproduction. Reproduction is part and parcel of natural selection except in one respect. If males and/or females exercise mate choice, which they often do, then one sex can induce changes in the other as a result of his or her mate choice habits.

Sexual selection, according to Darwin "depends on the advantage which certain individuals have over individuals of the same sex and species, in exclusive relation to reproduction" (Darwin 1871, p. 256). Darwin goes on to say that in all those cases where males have acquired a particular structure,

not from being better fitted to survive in the struggle for existence, but from having gained an advantage over other males, and from having transmitted this advantage to their male offspring alone, sexual selection must here have come into action. It was the importance of this distinction which led me to designate this form of selection as sexual selection. (p. 210)

Sexually selected traits can simultaneously be under natural selection, in which case the two forces will jointly act to regulate the outcome of the selection processes. The Peacock's unusually long tail is a classic example of such a process, where female choice lengthens the tail, and

natural selection, presumably due to pressures from predators, stops any further lengthening of the tail. Whereas "female choice and male modification" was the main mechanism offered by Darwin to explain how sexual selection operates, he did notice the active role of males in seeking mates through song, dance, and charm, which was accepted as part of the mating dance. Although Darwin was aware of male choice, he did not consider "male choice and female modification" to be an important mechanism, presumably because extreme cases of sexual modifications were more commonly observed in males, not in females.

Males and females make different investments into sex and reproduction. Males constantly seek mates, and females seem to be choosy about who they mate with. This difference is presumed to be the consequence of anisogamy. Anisogamy refers to differences in the size of male and female gametes or in the energetic cost of gamete production. Females expend large amounts of energy to produce fewer but larger gametes, whereas males produce smaller but plentiful gametes. Reproduction is therefore more costly for females, and it is in the best interests of the female to be choosy and select high-quality males to fertilize her few eggs. Males on the other hand have no such limitations and can mate frequently and indiscriminately. Gamete-based consideration of cost is not the only explanation for why females are more likely to exercise mate choice. An equally likely and probably a more correct explanation would be that male/female mate choices are two sides of the same coin. Males are always ready to mate before females, and are free to engage in frequent mating, which makes selection act stronger on males than females. Females may take longer time to get behaviorally/physiologically ready to accept mates. Also, one can question the assumption that male gametes are less costly to produce than female gametes. A single sperm may be less costly compared to an egg, but males do produce large amounts of sperm. In an energetic cost-based argument, it is the total cost of gametes that should matter, not the cost of individual gametes. As such, some fundamental issues regarding the sexual roles of males and

females and how the sexes interact to influence mating outcomes are debatable. Even after nearly a century and a half since Darwin, there still are discordant opinions on natural selection and sexual selection, such as what secondary sexual traits come under the category of sexual selection; how does male-driven sexual selection differ from female-driven (female choice) sexual selection; why do females choose or what is the basis of female choice, does sexual selection incur extra costs, do sexually selected traits evolve faster, and whether sexual selection is aligned with natural selection or does it oppose natural selection; and more.

Here an attempt will be made to shed light on these important questions, but it is not the intention of this entry to provide an in-depth review of all literature on sexual selection. Readers are directed to other entries that specifically deal with some aspects of sexual selection, sexual antagonistic coevolution, and sexual conflict.

Sexual Selection

Secondary Sexual Traits and Mate Choice

Darwin was convinced that many aspects of sexual dimorphism were the results of sexual selection. He began the chapter “Principles of sexual selection” by introducing and distinguishing between primary and secondary sexual characters (Darwin 1871, Ch. VIII). These terms were originally used by John Hunter, who described male and female reproductive organs, which are evident from birth, to be primary sexual traits, and secondary sexual traits were those that did not develop until animals approached breeding age. Darwin adopted Hunter’s terminologies but made some important functional distinctions. Darwin called primary sexual traits as those that are essential for and directly connected to the act of reproduction itself. Secondary sexual traits are not directly connected with the act of reproduction, but they are important to attract mates or to fight-off other members to gain mates, i.e., secondary sexual characters are central to the process of intra- and intersexual selection. By making this distinction, Darwin was able to explain how these

secondary sexual characters, such as elaborate antlers in deer or mandibles in beetles, by virtue of being used as weapons, evolved as a result of male-male competition. Similarly, he proposed that females may also choose the victors of male competition based on their strength and pugnacity or choose more ornamented males. He wrote:

There are many other structures and instincts [of males] which must have been developed through sexual selection- such as the weapons of offence and the means of defense of the males for fighting with and driving away their rivals – their courage and pugnacity – their various ornaments-their contrivances for producing vocal or instrumental music – and their glands for emitting odors, most of these latter structures serving only to allure or to excite the females. It is clear that these characters are the results of sexual selection and not of ordinary selection, since unarmed, unornamented, or unattractive males would succeed equally well in the battle for life and in leaving a numerous progeny, but for the presence of better endowed males. We may infer that this would be the case, because the females which are unarmed and unornamented, are able to survive and procreate their kind. (Ch. VIII, p. 210–211)

Darwin supported his case by presenting substantial evidence to illustrate two major features; firstly, mating is nonrandom in most cases, and secondly, males of most taxa are more “modified” compared to females. Nonrandom mating implies that some individuals succeed more in finding a mate and reproducing more than others. Darwin attributed this mating advantage to be the outcome of two major processes – male-male competition, where males competed with each other, often severely, in order to gain access to mate, and female choice. In either case, Darwin’s idea of reproductive success was based on quality – higher-quality males and female leave more offspring. Male-male competition is easy to envision – victors of a competition are able to have more mates and, thus, more reproductive success. With female choice, Darwin explains that females appear to choose males with certain “preferred” traits. Such males will reproduce more and leave a greater number of offspring compared to males who do not possess the “preferred” trait. Thus through female choice, females can shape the nature of modifications that develop in males of a population.

Darwin was criticized that he was mixing two types of traits – weapons that males use to fight among themselves and structures that males use to attract females and induce them to copulate (Mayr 1942). The critics claimed that only the latter category of traits can genuinely be the product of sexual selection. This interpretation is not correct because male-driven sexual selection implies “attracting females,” which includes *fighting for females*. The term male-driven selection here corresponds to what Darwin called “male eagerness and vigor” (discussed later in the entry). While Darwin does not specifically say so, his writings imply that male-male competition for females is more pervasive and stronger than competition for food. Once a weapon or a means of defense has originated, it can be used for both purposes – fighting for sex (females) or fighting for food. It is a different matter that the fights may not actually involve physical contact and may occur largely by threats and bluffs. Regardless, the consequences remain unaltered.

In theory secondary sexual traits can arise as a result male- or female-driven modifications and can be found in either sex with varying frequencies. Darwin made a strong point of the development of the senses in higher organisms which allow interaction within and between sexes. He marshaled impressive evidence from a variety of taxa to demonstrate that secondary sexual characters are not restricted to morphological traits but extended to instincts, odors, as well as visual and acoustic signals (Darwin 1871). Even though he focused on female choice and male modification, in theory, there are four possible processes:

- Male-male competition and male modifications (e.g., weapon)
- Female choice and male modifications (e.g., male ornaments)
- Male choice and female modifications (e.g., female beauty)
- Female-female competition and female modifications for attracting males (e.g., female beauty)

In this entry, we will mainly discuss the first three possibilities.

Male-Male Competition and Sexually Selected Traits: Armaments Versus Ornaments

Male-male competition can occur in two ways – direct male-male competition and indirect male-male competition. Here, we will briefly describe direct male-male competition (see entry on ► [“Sexual Selection via Direct Male-Male Interactions”](#) for more details). Indirect male-male competition, such as sperm competition, which Darwin was unaware of, is discussed elsewhere (see entry on ► [“Sperm Competition”](#)).

Darwin’s understanding of male-male competition was essentially complete. He realized that direct male-male competition occurs in two ways; one way is when males physically battle one another in order to gain access to females (“the law of battle”). The other way is males will try to outcompete one another by engaging in visual, acoustic, or behavioral displays to attract females. Darwin realized that male-male physical competition was a major reason for the evolution of male weaponry or armaments, such as large antlers or tusks or even body size. Darwin envisioned a process where depending on the trait used in combat, e.g., antlers or body size, the males with larger antlers or large body size are most likely to be victorious. Using the analogy of how “...man could improve the breeds of his game-cocks by the selection of those birds which are victorious in the cockpit,” he deduced that the most vigorous or strongest males or those with the best weaponry have a distinct advantage in battles and thus reproduce more (Darwin 1871). The offspring of these victors will inherit the superior traits of their father and will be poised to be successful in their mating efforts. Male elephant seals are a classic example of male-male competition and body size evolution. Male elephant seals compete intensely for territory and for dominance over a harem of females, and larger males have greater success in accomplishing both.

Male-male competition by display is easily seen in birds, where rather than engage in direct battle, male of many species compete by displays of plumage, song, or dance. Darwin described how several species of birds would congregate, and males would “display with the most elaborate care, and show off in the best manner, their

gorgeous plumage; they likewise perform antics before the females, which standing as spectators, at last choose the most attractive partner” (Darwin 1859). This form of a more “peaceful” male-male competition, where the most attractive male leaves more offspring, results in the evolution of “ornaments” rather than armaments. Here “ornaments” is used as a general term to describe the color or morphology of plumage, acoustic signals such as songs or nonvocal sounds, or dance.

Other forms of male-male competition, such as alternative mating strategies, have also been documented. Males within some species avoid encounters with aggressive, dominant males and gain access to females by deviating from the customary mating strategy – they engage in “sneaky” mating behaviors. For instance, in the sexually dimorphic marine isopod *Paracerceis sculpta*, larger alpha morph males defend harems to monopolize females. Smaller beta morph males are about the size of females and gain access into harems by mimicking female behavior. In the horned beetle, nutritional differences cause some males to develop larger horns. These large-horned males defend females by guarding the entrance of the tunnel in which the female feeds. Smaller males that lack horns or have very small horns gain access to females by digging a new tunnel and bypass the guarding male. Such male-male competition via alternative mating strategies is not common but has been found in a variety of taxa.

Female Choice and Male Modification

One of the key observations Darwin made was that males were more “modified” relative to females across species. He was not only referring to the remarkable diversity of male secondary sexual characters, but he was also referring to the variation within males of the same species. Darwin had previously noted that variation was central to the evolutionary process by natural selection (Darwin 1859). Similarly the within species variation in male secondary sexual characters is the substrate for female choice. In fact, Darwin realized that the idea of female preference or choice would be moot if males did not vary in their efforts to pursue and/or if there was no variation in the traits that females preferred (Darwin

1871). The very fact that variation exists justifies that females have the opportunity to choose. As such, he deduced that male modifications were a result of female choice, if not by male-male competition. Just as the more vigorous males have the opportunity to select-out the less vigorous males through male-male competition, females have the opportunity to select males with certain modifications.

Darwin’s theory of female choice was received with some confusion and rejection by his contemporaries (including Wallace and Huxley) and was sidelined for the next several decades as well (Mayr 1942). The reason was that male-male competition was quite obvious, but female choice was not only unclear, but it was immediately linked to human-like esthetic behavior in animals despite Darwin’s assertions that female preference only reflects an arbitrary ability to discriminate. Another problem is that Darwin never really explained how female preference evolved. To begin with female choice, females will need to already possess or somehow acquire a “preference” for specific male traits or set of traits – this matter remains a conundrum.

Evolution of Female Preference

Several decades after Darwin, Ronald Fisher (Fisher 1915; Fisher 1930) proposed an ingenious explanation for the evolution of female preference. Fisher begins his verbal treatise by perceptively explaining that:

an animal’s struggle for survival is not only measured by the number of offspring which it produces and rears, but also by the probable success of these offspring. (Fisher 1915, p. 185)

So it would be important to select a mate that is more likely to produce successful offspring. In his verbal model, Fisher conceived of a heritable male trait that was initially favored by natural selection. He surmised that the male trait may or may not by itself have any value to a female, but a female may merely associate that trait with the male’s vigor. The male’s vigor could reflect his fitness as a potential mate who would produce successful offspring. A female that makes such a choice will then likely have more success and leave more offspring. The important idea here is that while a

female's preference for a male trait will modify the male trait, e.g., the male's tail gets longer; the female's preference is also modified such that females in subsequent generations will prefer males with longer tails. So in Fisher's model, the trait is firstly favored by natural selection, and is then additionally favored by sexual selection, which will reinforce that such a trait increases in frequency in a population. Moreover, as Darwin deduced, sons will inherit the father's trait and daughters inherit their mother's preference for the male trait. Thus, the evolutionary trajectories of these traits become correlated and will evolve in tandem. Such correlated selection can result in a rapidly accelerating process that will cause the male trait to become exaggerated until natural selection opposes its further elaboration.

However, Fisher was aware of traits such as the peacock's tail, and like Darwin, he too realized that such a trait would debilitate rather than facilitate the bird's survival. To explain the evolution of such exaggerated traits, Fisher (1930) proposed a second component to his theory, which he dubbed the "runaway process." He proposed that:

as long as there is a net advantage for further plumage development, there will also be a net advantage in favor of giving to it a more decided preference.

The two characteristics affected by such a process, namely plumage development in the male, and sexual preference for such development in the female, must thus advance together, and so long as the process is unchecked by severe counterselection, will advance with ever increasing speed. In the total absence of such checks, it is easy to see that the speed of development will be proportional to the development already attained, which will therefore increase with time exponentially, or in a geometric progression. Thus in any binomic situation, in which sexual selection is capable of conferring a great reproductive advantage, the potentiality of a runaway process, which, however small the beginnings from which it arose, must, unless unchecked, produce great effects, and in the later stages, with great rapidity. (Fisher 1930, p. 137)

In this argument Fisher deduced that persistent female preference is likely to counteract the limitations imposed by natural selection, thus displacing the sexual selection-natural selection equilibrium. So if female continued to prefer males with longer tails, then the process may

"runaway" unchecked by natural selection, and male tail lengths can reach exaggerated proportions in a short number of generations. Females will prefer males with exaggerated characters not because they are better in quality but because the sons of the female will be more attractive to females ("sexy sons"). Fisher's intuitive insights were largely ignored until decades later when genetic models explicitly corroborated the plausibility of Fisher's theories (O'Donald 1962; Lande 1980).

Cryptic Female Choice

Sexual selection via female choice became quite popular in the 1970s and 1980s, and substantial research revealed that female choice can be a major driving force that shapes the nature of male modifications in a species (Andersson 1994). Eberhard and Cordero (1995) proposed the idea of cryptic female choice, which they defined as "female behavior, physiology, or morphology that selectively biases paternity in favor of some conspecific males and against others, after copulation has already begun" (Eberhard and Cordero 1995; Eberhard 1996). Females can therefore modify the outcome of male mating success. Eberhard's idea of cryptic female choice was an important development in sexual selection research since it explained the remarkable diversity of not-so-easily observed male modifications, such as genitalia (see entry on [► Evolution of Genitalia, The](#)). Cryptic female choice also offers an explanation for how females may be able to overcome male coercion during mating, i.e., post-copulatory selection.

Why Do Female Choose?

Despite the strong theoretical framework that was established on the evolution of mate preferences, some questions remained unanswered. How did female preference arise in the first place and was then selected for? An explanation to this question has never really advanced beyond Darwin's and Fisher's broad assumptions. Furthermore, there is the question of why *do* females choose? Do they receive benefits from preferring certain males, or

is preference based on some sensory perception regardless of benefits to the female? These questions received considerable attention and spawned the development of distinct theories and models that have been under considerable debate for the last few decades. The models to explain how and why females choose may broadly be placed under four categories based on the mechanisms at play: direct benefits model, indirect benefits model, sensory drive model, and “other” models, each of which are driven by several processes.

The direct benefits model is the least controversial of all, given its relative simplicity. Under this model, females would prefer to choose mates who provide direct benefits to the females, such as territory, nuptial gifts, parental care, etc. Direct selection can occur in several ways, for instance, if females choose mates who are more conspicuous than others, they reduce time spent in finding mates and avoid predation risks or if female preference for particular males has other unrelated favorable consequences, such as producing more offspring (Markow et al. 1978). In general mate choice via direct selection will evolve if females prefer mates who increase female fecundity or survival.

Indirect benefits models apply to taxa where females do not receive direct benefits yet seem to show a preference for male ornaments. Indirect benefits models are more complex and can be divided in two major categories based on the adaptive and nonadaptive schools of thought – indirect selection via “good genes,” and indirect selection via coevolutionary processes, i.e., the Fisherian process. Before explaining the models, a brief mention of “indicator mechanisms” is necessary. Indicator mechanism derives from the widespread observation that costly secondary sexual characters are likely to be well developed in healthier individuals and thus may serve as “indicators” of male quality. Fisher (1915) included this idea in his theory but was largely ignored until Williams (1966) formalized the term.

The “good genes” hypothesis belongs to the adaptive school of thought and stemmed from (Zahavi’s 1975) handicap principle. Zahavi claimed that males with costly exaggerated characters must be of higher genetic quality since they have passed the test of natural selection, i.e., they are

able to maintain the exaggerated trait despite the fact that it reduces their chances of survival (i.e., their viability). This idea spurred the development of the condition-dependent indicator model. Under this model, the development of the male’s indicator traits is condition dependent, i.e., dependent on the male’s genetic quality and viability. The condition dependency makes the ornament a reliable indicator for females to judge male quality. One of the classic case examples for condition-dependent good genes indicator is Hamilton and Zuk’s (1982) study on birds. They postulated that healthier males will be more resistant to infections and thus be able to maintain elaborate plumages. Conducting an extensive survey of blood parasites in American passerine birds, they found that males with brighter plumage did have lesser parasitic infections. Such studies lend empirical support to the idea of the evolution of indicator traits and that perhaps females may use them to choose mates.

Fisherian process exemplifies a nonadaptive process, where female choice evolves by indirect selection via the Fisherian process (see above). It is interesting that despite the traditional dichotomy between the “good genes” and Fisherian model, both rely on female preference for an indicator trait, but in the Fisherian process, the trait may be random and mate choice evolves via females mating with “arbitrary” attractive males to produce “sexy sons.” Under the “good genes” process, the trait signals higher fitness, and mate choice evolves via mating with attractive males who have higher viability. Despite this dichotomy, the two may not be mutually exclusive, because if female preference and male trait have a heritable genetic basis, then a Fisherian process is implicit in any form of indirect-benefit model.

Sensory drive broadly refers to how selection on sensory systems can influence the evolution of traits (including mate choice). It comprises of several models such as sensory exploitation, sensory trap, receiver bias, etc. (Endler and Basolo 1998). Here, genes affecting female mating preferences may also influence other aspects of survival, such as predator avoidance, foraging etc. (i.e., via a pleiotropic effect). In such a case, selection on sensory perceptions that are not necessarily related

to mate choice but to other aspects of life (foraging, predation) can drive biases in mating and can be confused with the traditional “mate preference.” Essentially, females may associate male traits with predation or even food availability, or males may exploit these associations to attract the attention of females. Such sensory mechanisms have been implicated in the diversification of South American guppies, where female preferences coincide with predation intensity or even food coloration. For instance, females in high predation areas prefer males with inconspicuous color patterns and vice versa. Similar trends have been found in the African cichlid fish. Sensory drive can be quite powerful because it varies with the environment, spatially and temporally. Such sensory mechanisms may also initiate and drive the direction of mate choice evolution via Fisherian processes and even provide the foundational basis for the “good genes” system because in essence, the evolution of sensory systems, signals, and behavior are coupled and will coevolve.

Other models. Another class of models suggests that females may choose more genetically compatible males. This model proposes that by choosing genetically dissimilar males, females may receive benefits such as fitter offspring by increasing heterozygosity and/or silencing dominant deleterious alleles. A popular example is how new combination of MHC alleles can increase fitness. A more recent hypothesis suggests that female mate choice can evolve due to sexual conflict or sexual antagonism. Here, female choice evolves via the evolution of female resistance to males who try to entice or force females into mating. Males in turn may evolve additional strategies to manipulate female choice, which can lead to sexually antagonistic coevolution or sexual arms race, which may resemble a “runaway process,” or in this case, a “chase away process” (see entry on ► [“Sexual Conflict”](#)).

Male Choice, Female Modification, and the Theory of Male Sex Drive

The traditional popularity of female choice may have overshadowed the role of males in the

mating game. Even Darwin appeared to emphasize on how females choose males. However, Darwin repeatedly mentions the heightened sexual activity of males and remarked that “males with their superior strength, pugnacity, armaments, unwieldy passion and love songs, are almost always the more active and most often, the initiators of sexual interactions” (Darwin 1871). Darwin must have seen that male-male competition was the result of male’s “sexual drive” and that this drive will work even in the absence of direct male-male combat. He used the expressions male “vigor” and “eagerness” to describe the role of males but did not formalize these terms as traits that may be under selection. Fisher also invoked male “vigor” (see above) in his theory. Yet even though Darwin coined the term “female choice,” he failed to clarify male “vigor” and “eagerness” to be the male counterpart of “female choice.”

Darwin appears to divide males into two groups based on their mating behavior. In species with direct male-male competition, males may develop strength and weapons for fighting. In these species, the winner takes the female. The second category of males have showy traits that they presumably use to display and charm females. The latter is how Darwin visualized female choice to work, particularly in species with showy traits such as in the peacock. While Darwin noted the heightened activity of males during mating, he did not see that all males are alike in one respect, i.e., they are all driven by what a recent theory has termed male sex drive or male-driven sexual selection (Singh and Kulathinal 2005). While seeking mates, males, often unrelentingly, make use of all their resources – ornaments or armaments to secure females.

Male-male competitions and male displays are not two alternate states of mating strategy, but they represent two ends of the male lifestyle spectrum. Males can use their armaments or “showy” traits to intimidate other males just as they can use it to coerce females into submission. Physical strength and aggressive behaviors that males develop through male-male competition can also be used in male-female sexual interactions. From

the males' point of view, combining charm and coercion may be a winning strategy, and thus all male displays maybe viewed directly or indirectly as mixed with threats of physical force.

Male sex drive is described as the driving force behind the heightened, male-driven sexual activity during the course of mating. This would include, but is not limited to, sexual desire and libido, male-male competition for females, searching for mates, courting or even harassing females, song and dance, mounting and mating, controlling copulation, sperm quantity and quality, mate guarding, and readiness for remating. Male sex drive encompasses all efforts – physical, material, and psychological – made by males in order to procure mates. Since there is variation in these traits, they will be under selection via male activity or via female choice. As Darwin put it, the power to charm females has been in some instances more important than conquering other males in battles. Male charm and male aggression against females are invariably mixed and may range from pure charm to pure aggression. Male sex drive theory posits that sexual selection is stronger in males in all aspects of mating. Moreover, male sex drive and female choice together makes sexual selection a self-reinforcing, perpetual force of evolutionary change.

Sexual Selection and Adaptation

It is well understood that natural selection generally acts to increase all aspects of organism fitness, facilitating organisms to survive and reproduce in a given environment. The role of sexual selection, on the other hand, with respect to the general organism fitness remains controversial. As is evident in the previous sections, much of the intellectual debate in sexual selection is the evolution of maladaptive traits, such as the peacock's tail, and since Darwin, the opposing forces of sexual selection and natural selection have been implicated in theories and models. This has led to disputes whether sexual selection will eventually reduce population viability, and possibly cause extinction, or if sexual selection augments natural selection.

Under the “good genes” model, natural and sexual selection can complement one another since females choose males of higher fitness and thus produce high fitness offspring. This was also Darwin's (1859) thinking when he stated “Amongst many animals, sexual selection will give its aid to ordinary selection, by assuring to the most vigorous and the best adapted males the greatest number of offspring.” A fundamental requirement for this is that male secondary sexual traits must be “honest” indicators of genetic fitness (e.g., Hamilton and Zuk 1982). Under “good genes” and honest indicator conditions, several theoretical models show that sexual selection does increase overall fitness by increasing the spread of advantageous alleles, by removing unfavorable mutations in the genome, and by speeding up the process and the rate of adaptation (e.g., Lorch et al. 2003). These effects can increase population fitness and even confer advantages to maintaining sexual reproduction (Agarwal 2001). Empirical support, however, is mixed with some studies showing that sexual selection augments natural selection and others showing that sexual selection opposes natural selection and impedes adaptation to new environments. These contradictory reports raise the need for more comprehensive studies because the nature of sexual selection, and the costs and benefits of sexually selected traits can vary across environments and also change with changing environments.

Sexual Selection and Rapid Evolution

Gradual change is the hallmark of evolution by natural selection. This is generally thought to be due to the gradual nature of changes in the environment, biological and non-biological, but more precisely due to the limit on variance in fitness (Fisher 1930). The last 50 years of work in population genetics has shown that, excluding isolated-inbred populations, genetic variation is not a limiting factor in evolution. Evolution is driven by ecological opportunities as shown by the rapid response of beak sizes in Darwin's finches. Gradual evolution does not mean uniformity of rates over time, but instead variable/episodic evolution

in molecules and morphology is a norm and not an exception in modern evolutionary theory.

Sexual selection, on the other hand, provides a mechanism for rapid evolution. Even Darwin and Fisher realized this. Unlike viability, which follows environmental changes but within limits over time, sexual selection depends on mate choice and mating frequencies that involve sexual interactions between males and females – a feature that remains persistent generation after generation. All else being equal, the factors affecting mate choice (female choice, sexual arm race, and male sex drive) can illicit changes in every generation, which would make sexual behavioral characters, e.g., desire to mate, to become reenforced over time.

Evolutionary studies have shown that sexual selection is an important factor in generating sexual dimorphism in a variety of molecular, morphological, physiological, and behavioral traits. Molecular evolutionary studies are shedding light on how sexual selection has shaped male and female specializations in the genome. Recent studies have shown that sexual selection is an important factor in generating sexual dimorphism in patterns and rates of molecular evolution in genomes. Some of these observations are as follows: (1) A large proportion of the annotated genes in the genomes of *Drosophila* and other organisms show sex-biased expression, indicating that sex- and reproduction-related (SRR) genes represent a significant component of the genome; (2) SRR genes show elevated levels of tissue-specific expression compared to non-SRR genes; (3) a high proportion of SRR genes displays accelerated divergence in sequence and expression, as well in loss/gain of genes; and (4) male-specific molecules like testis-specific genes, seminal fluid proteins (SFP), and spermatogenesis genes show lineage specific bursts of accelerated evolution and positive selection. These trends have been recently demonstrated in an increasing number of taxa. These results show that sexual selection is an important force driving the rapid divergence of male SRR genes and that accumulation of “male-fitness enhancing” mutations are likely due to male sex drive. Note that, in birds and Lepidoptera, female-biased genes evolve faster

since they are the heterogametic sex. It is important to note here that not all SRR genes show higher divergence; for instance, genes involved in sperm and egg structures and functions remain constrained in their rate of evolution.

Sexual Selection and Speciation

Speciation is well recognized to be one of the fundamental processes that generate biodiversity and understanding how speciation occurs remains one of the greatest puzzles in evolutionary biology. Darwin was aware that sexual selection can play a potent role in the origins of species. Indeed, he dedicated an entire book explaining how sexual selection influenced divergence of sexual characters, creating “varieties,” “subspecies,” and “allied (closely related) species,” and how divergence and variations in man were a result of sexual selection (Darwin 1871). Post-Darwin however, the role of sexual selection in speciation, was considered secondary since divergence of sexual characters and the establishment of reproductive isolation was considered to evolve gradually when populations were geographically isolated from one another, i.e., in allopatry (Dobzhansky 1937; Mayr 1942). This was also a time when the mechanism(s) of sexual selection was intensely debated (see above), and mate choice, species-recognition, and speciation were viewed as fundamentally different, rather than a continuum as we see it today (i.e., all three phenomena incorporate the same processes).

Several studies later emerged and supported the idea that divergence of sexual characters due to sexual selection can be a powerful force that can not only initiate but also accelerate the process of speciation. The rapid origins of the remarkable diversity of the Hawaiian *Drosophila* attracted considerable attention to the possible role of sexual selection in speciation. Studies proposed that via concurrent evolution of male signal displays and female preferences, species can rapidly radiate into new behavioral niches, rather than into geographical niches (Ringo 1977). Lande’s work (e.g., 1980) was most influential in establishing the idea that sexual selection can cause speciation.

In his models, as long as there is genetic variation for male traits and female preferences for that trait, then assortative mating will lead to speciation in a Fisherian manner. West-Eberhard (1983) wrote an influential review and provided detailed arguments of how social evolution, including social competition for resources and mates, including intrasexual and intersexual selection, can lead to rapid divergence of social and sexual signals even in sympatry. She reasoned that under social evolution, sexual selection will be strong and that a runaway process can be initiated by any number of behavioral, genetic, or ecological factors. Thus sexual selection is certain to have played a role in speciation across animal groups.

One of the ways to test that sexual selection causes population behaviors to diverge to the point that speciation can occur is to show that (1) male signals must be divergent across populations and species, (2) females must prefer local signals to heterospecific signals, and (3) male signal divergence across populations must correlate with genetic divergence between populations. Ryan and coworkers made important contributions by demonstrating considerable variations in male signals and female preferences for these signals in anuran populations. Ryan and Rand (1993) demonstrated that sexual selection and behavioral isolation occur via similar processes. These processes were previously considered to be unconnected. They showed that female tungara frogs (*Physalaemus pustulosus*) respond to both heterospecific and intraspecific signals, but females nonetheless prefer the intraspecific signal. Later, Boul et al. (2007) demonstrated that all three test criteria in are met in *Physalaemus petersi* (a sister species to *P. pustulosus*) to substantiate that sexual selection does indeed drive speciation.

Comparative studies have traditionally played an important role in suggesting that sexual selection influences speciation. Two types of comparative tests have been useful. Darwin noted that (1) secondary sexual characters appeared most pronounced in species-rich (speciose) animal groups, and (2) sexual characters are the most divergent across closely related species (Darwin 1871). Tests of the first kind were done by

Barraclough et al. (1995), who compared 20 recently diverged sister species of passerine birds that either had different color patterns between males and females (sexual dichromatism) and those that did not (monochromatic). Sister species, in theory, have accumulated variations for a similar amount of time. If Darwin was right, then one would expect the sexually dichromatic species to be more speciose than the monochromatic birds – which is what Barraclough et al. (1995) found. This comparison was later extended to show that promiscuous bird taxa tend to be more speciose. However, recent tests of same issue across mammals, birds, butterflies, and spiders remain inconclusive with some supporting Darwin's observation and others finding no evidence for it.

Research on the second test – that sexual characters are most divergent across closely related species – has been far more consistent in supporting the role of sexual selection in speciation. Darwin (1871) himself gathered plenty of data to demonstrate that sexual characters are most divergent between species and emphasized on female choice as a driving force. Eberhard (1985) compiled an impressive array of data showing that male genitalia are one of the most divergent characters across the animal kingdom. He later attributed this trend to be primarily due to cryptic female choice (Eberhard 1996). Arnqvist and Thornhill (1998) argued that genitalia evolved rapidly and divergently due to sexual conflict. Jagadeeshan and Singh (2006) proposed an interaction between male-sex drive and female choice. The rapid evolution of male genitalia has been extended to a variety of taxa other than insects, but the evolution of female genitalia is only recently beginning to receive interest.

The advent of gel electrophoresis and subsequent advances in molecular methods revolutionized evolutionary research. Singh and coworkers were influential in bringing about interest into the molecular signatures of sexual selection (reviewed in Singh and Jagadeeshan 2012). In 1988 Coulthart and Singh published a series of papers showing that reproductive proteins showed little variation within species but large variation between species. Later it was demonstrated that

reproductive proteins evolved more rapidly and divergently compared to nonreproductive proteins. A long line of studies across taxa subsequently demonstrated that reproductive genes, particularly male SRR genes, evolved fast compared to nonreproductive genes. This trend also brought new light into Haldane's rule (Haldane 1922) that when hybrids are produced, the heterogametic sex is either inviable or sterile. New insights continue to emerge from comparative genomic studies. All of these studies provide a strong molecular foundation that sexual selection influences speciation. However, there is a lack of consensus regarding the mechanisms, and many important tenets of speciation by sexual selection remain to be demonstrated. There is emerging consensus, however, that in most cases, sexual selection will interact with natural selection and species ecologies in various ways to influence speciation.

Sexual Selection and the Problem of Males

Sexual selection by definition implies selection through mate choice performed by males and females and the two sexes are a given. In other words sexual selection does not pertain to the important question "Why males, or why are there males?" Why males, is part of the larger question: why there is sex? The answer, provided by population genetics, is that sex essentially means variation and variation is good for evolution. The advantage of variation must be large enough to compensate for what is called the twofold cost of sex (producing males and transmitting only half the genome to offspring) and to counteract the establishment of self-fertilizing mutations in populations. The problem of males is worse than the problem of sex because as opposed to asexuals or hermaphrodites, in species with males and females half of the population does not reproduce, other than contributing gametes. Given the high cost of sex, advantage of variation is not a satisfactory answer to why sex is so prevalent.

The twofold cost of sex is based on evolution in a closed population comparing unisexual (self-

reproducing) versus bisexual reproduction. If we move away from the advantage of variation argument and look at the sexual behaviors and lifestyles of males, then the evolutionary purpose of males becomes clearer. With their dominance, agility, and mobility to explore new territory and new resources, one wonders if males have found a way to invade the (asexual) genome, to induce molecular changes that make females dependent on male contribution, and to evolve an aggressive lifestyles that favors males often at the cost of females – all of which may add up to more than what is needed to compensate for the cost of producing males. Males, driven by their "eagerness" to mate may have turned themselves into nature's drivers of evolution by self-reinforcing, repeated evolutionary change; this occurs through selection for exaggeration of sexual desire, which in turn promotes mate seeking, competition, copulation, mate guarding, and everything else. Individually males get the benefits of mating; collectively they augment overall population and species fitness. Sexual selection through sex drive offers a powerful mechanism for the maintenance of males and for the success of higher organisms in general.

Cost of Sexual Selection

We are not concerned here about the cost of males or the maintenance of sexual reproduction but only about the cost of sexual selection or the cost of mating. Mating can be costly to females. Males and females are different and unequal in their biological endowment with respect to sex and reproduction. This is likely due to anisogamy and the associated difference in energetic requirements to produce gametes. Males can produce larger number of smaller gametes and engage in repeated mating. Females on the other hand produce limited number of eggs and do not mate as often as males do. Thus a male's fitness is directly proportional to the number of mates he can garner. The resulting sex differences in reproductive interest can be detrimental to females due to male harassment and the harmful effects of multiple mating.

Notwithstanding, it is important to point out that with respect to linking the origin of sexual dimorphism on anisogamy, it may not be the differences in gamete size per se that drives male-male competition. Indeed, egg sizes vary considerably between animals but so can sperm. *Drosophila bifurca* is only a few millimeters in size, but it produces sperm 6 centimeters long. The heightened male activity and male-male competition may originate from qualitative sexual differences in the transmission of genetic information between the sexes (excluding sex chromosomes or mitochondrial DNA). Life is an unbroken chain through females (or hermaphrodites), but not males; male contribution is necessary but limited to a reduced set of chromosomes. Females, on the other hand, transmit through their eggs, a haploid set of chromosome plus essential mRNA and proteins needed to kick start embryogenesis. Furthermore, gametes have to find each other. This is achieved through mate recognition, mate choice, and mating, followed by movement of sperms toward the eggs. Eggs are sedentary; sperm are mobile.

Aggressive male mating behavior means stronger selection on males since all males do not get to mate. Male-male competition provides a mechanism for the purging of male-deleterious mutations and the accumulation of male-beneficial mutations, even if they may be harmful to females. *Drosophila* male accessory gland proteins (Acps) are a good example of the latter. Male Acps are transmitted with the sperm during copulation. Many of these proteins are known to affect females in a variety of ways including modifications to female remating behavior, life span, egg-laying, and overall fitness (Wolfner 2007).

Female choice can also impose costs on sexual selection. Strong female choice linked to a trait such as the peacock's tail (irrespective of whether it is a condition-dependent or condition-independent indicator trait) will lead to its exaggerated expression and associated cost not only in energetic terms but also in terms of negative effects on the male's fitness. The cost of sexual selection is real, and it is irrelevant that males gain more mates and success. Even if disassociated from female choice, male-male competition for

mates can lead to exaggerated expression of a male trait as shown by the length of deer's antlers or the large size of elephant seals (Andersson 1994). Indeed, sexual reproduction is often wasteful and goes against the theory of optimality.

Beside the cost of mating, sexual conflict and sexually antagonistic selection (see chapter on these topics) can lead to unequal fitness of the sexes and lower overall population fitness. In theory both sexes should have equal fitness, but in reality this may not be possible due to the lack of mechanisms available for females to counter respond. Alternatively it may be possible to make up for such loss of population fitness through trans-generational gain of fitness that is driven by male reproductive longevity. For instance, loss of fitness due to death of females (caused by male harassment or toxic seminal proteins) can be compensated by males mating multiply with females from different generations, i.e., similarly aged females and with younger females from the next generations (Jagadeeshan et al. 2015).

Sexual Selection and Human Evolution

Darwin's theory of evolution by natural selection, or descent with modification, affected how humans view themselves, and the theory faced stiff opposition. Arguments were made by many to make humans exceptional, particularly in the area of language, art, and choice. Since Darwin did not believe in human exceptionalism, it is believed that one reason why Darwin pushed the idea of sexual selection (through female choice) was that he wanted to show that "choice" was not a prerogative of humans, a position promulgated by theologians, and that other animals can also exercise choice. Furthermore, Darwin did not believe that the origin of human races could be explained by natural selection alone, a position no evolutionist holds now. Darwin went on to conclude that "of all the causes which have led to the differences in external appearance between the races of man, and to a certain extent between man and the lower animals, sexual selection has been by far the most efficient" (Darwin 1871).

Darwin pushed the idea of female choice and esthetics even though he was aware, as were most of his contemporaries, that there appears to be little evidence for female choice in humans. And this is the reason why Darwin's theory of sexual selection was rejected by his contemporaries including Russell Wallace. Wallace suggested a utilitarian role for coloration and argued that the reason why female birds are dull is that dullness provides females and their eggs protection from predators. While Wallace's protective coloration became accepted, his theory did not explain why males were bright and conspicuous.

Darwin flip-flopped on men choosing women and wrote in *The Descent of Man*: "In civilized life man is largely, but by no means exclusively, influenced in the choice of his wife by appearance" and then contradicted himself, "Civilized men are largely attracted by the mental charms of women, by their wealth, and especially by their social position" (Darwin 1871, p. 338). While evolutionary psychology literature is full of examples of female choice, in which adaptationists argue that "it makes sense" from the female point of view, the original observations about men have not changed: that men have a strong *desire for sex*, that they have *innate feeling for beauty*, and that it is largely men who exercise *selection in choosing mates (women)*. The sexual axis of "desire-beauty-choice" is largely a self-reinforcing male-driven process.

Mating Systems, Mate Choice, and Female Beauty

To see if sexual selection has played an important role in human evolution, we need to look at the evolution of mating system. The role of sexual selection in human evolution can be partitioned into three phases that may reflect changes in mating strategies: preagriculture hunter-gatherers, agricultural-settled populations, and modern populations. Human mating system has evolved from being promiscuous to polygamous to monogamous. Promiscuity would have allowed room for mate choice and sexual selection to operate through both sexes. Polygyny would have been far more common than polyandry, and it would have allowed room for male choice

where resource-rich males would have monopolized beautiful females. Even monogamy allows room for male choice in the selection of brides in patriarchal societies. With the rising role of female choice in modern (western) populations, true sexual selection in the Darwinian sense has begun to play an important role, but male choice for brides still reigns in much of the world.

One of the most important aspects of human mating systems is the evolution of male desire (male sex drive) for younger females and female beauty. Male choice for younger females would select for early sexual maturity and early reproduction and male choice based on beauty would push for the concentration of "beauty traits" in younger females. Besides facial features, many of which would have evolved to become population, country/culture specific, sexual selection has played a major role in the evolution of skin color in mixed modern populations. While traits affecting survival evolve in response to changes in environmental elements, sexual desire evolves through repeated male-male competition and/or through male charm and/or coercion. This makes the evolution of sexual desire or male sex drive unlike any other trait.

Male Choice and Female Modification in Humans

The role of male choice and female modification extends beyond facial beauty and skin color. Evolutionary consequences of male-driven sexual selection can be costly to females, and it can potentially reduce female fitness. A recent study showed that male preference of younger mates would deprive older females from reproduction and its associated biology, which in turn would lead to the accumulation of deleterious mutations affecting female fertility, eventually giving rise to menopause (Morton et al. 2013). The important point of choosing younger mates here is that it not only provides a genetic theory of menopause, but it also shows that human (mating) behavior can make deleterious fertility mutations behave as neutral and accumulate in the population. Sexual selection by mate choice has been consequential to the evolution of female fitness by influencing the evolution of traits such as menopause,

maternal mortality, loss of estrus, breast size, hip size, and others.

Conclusion

Sexual selection, according to Darwin “depends on the advantage which certain individuals have over individuals of the same sex and species, in exclusive relation to reproduction” (Darwin 1871, Vol. 1, p. 256). Sexual selection is the result of competition for mates. Since males generally compete for females, Darwin thought that female choice is a major driving force of evolutionary change. The issue of how and particularly why female choose remains a contentious issue but by no means undermines the progress that has been made. Any trait that becomes the basis of mate choice, will for various reasons, come under selection as a result of changes in mating behavior. Animals have evolved a large repertoire of mate selection mechanisms or mating rituals in which males and females make use of various traits (song, dance, calls, size, color, plumage, and odor) to select mates. The development of several valid theories of mate choice or sexual conflict, male sex drive, etc. is evidence of the complexity of the field. The unresolved debates can only mean that the field of sexual selection is still wide-open and avails rich opportunities for research in a technologically advancing world. Due to the traditional popularity of female choice since Darwin (males fancy to be the object of female desire), male choice has been given little attention. Sexual conflict has provided an alternative, but the male’s role in sexual selection has been largely restricted to male-male competition. Yet Darwin himself was fascinated by the “eagerness” and “vigor” of males during mating. These qualities can themselves be under selection as Darwin and Fisher deduced – that the most vigorous males succeed or that females choose a trait that indicative of a male’s vigor. Research in this field is beginning to receive some attention and the results are promising.

Overall, a large variety of data now support the idea that sexual selection is responsible for many

of the spectacular sexual dimorphisms and species diversity across animal and plant groups. Molecular studies have uncovered the impact of sexual selection on the genome as a whole and have shown that sex- and reproduction-related genes have diverged faster than other genes and male-biased genes faster than female-biased genes. The molecular data support the conclusion that besides female choice, male sex drive has been a powerful force of evolutionary change. In the end, much progress remains to be made and much more to be learned, and Darwin’s intuitive framework laid out a century and half ago will continue to steer the exciting progress that will be made in sexual selection research.

Role of sexual selection in human evolution goes beyond mate choice and reproduction; sexual selection has become a permanent feature of human society and culture. All through history – particularly religious history – man has fought against sexual desire at every level and in every possible way while at the same time succumbing to it as an addict to his substance. Man has wrangled with his sexual nature by denying it, but advances in sexual selection and psychology have turned the tide. Religious and social stigma can no longer ignore the fact that man is driven by sexual desire and that male sex drive is a major force of evolutionary as well as social change. Sex defines man’s nature and sexual selection and mate choice are essential to the understanding of human nature – body and mind, individual and society.

Charles Lyell

Ian J. Smalley
School of Geography, Geology & the
Environment, University of Leicester,
Leicester, UK

Charles Lyell was born at Kinnordy House, near Kirriemuir, a few km SW of Aberdeen, in Forfarshire (now Angus), Scotland, on

14 November 1797. He died in London on 22 February 1875 and was buried in Westminster Abbey. He was joined there 7 years later by his friend Charles Darwin. Significant pioneers of geological science and the study of evolution lie together. He was the oldest of ten children; the family moved south to the New Forest region, near Southampton where he lived when he was young. At the age of 19, he enrolled at the University of Oxford (Exeter College) and graduated BA in 1819 and MA in 1821. He was lured into geology, to a large extent, by Poulett Scrope and spent his life dispensing geological knowledge. His first paper, in 1825, was on a serpentinite exposure in Canty Burn along what is now known as the Highland Boundary Fault. The Canty exposure is only 3 km from Kinnordy. His great work was the *Principles of Geology* which commenced publication in 1830 and was produced in a variety of editions throughout his life (Lyell 1830–1833). The 12th edition was in print at the time of his death. He is associated with Charles Darwin; he wrote the famous letter to Darwin in 1836, just after the return of the *Beagle*, urging him to avoid all administrative tasks and to concentrate on scholarship. He also cooperated with Joseph Hooker, to have the outline of the theory of evolution, sketched by Darwin in 1844, published along with Alfred Russell Wallace's version of the same conception, by the Linnaean Society in 1858 (see Partridge 2015).

Biobibliographical Studies

There are several excellent biographies; Bailey (1962) presented him as a “British Man of Science” in the Nelson series. Wilson (1972) reported the early years (to 1841) in great detail and added useful accounts of Lyell in America (Wilson 1998). He also published a valuable study of Lyell's journals on the species question (Wilson 1970). The best appreciation of Lyell is perhaps that by Secord (1997). This appeared as the introduction to the Penguin edition of *Principles*. The Penguin edition is a superb version of the *Principles*; Secord has carefully edited the three-volume work down to a handy one-volume paperback; the

essence is retained, but some unnecessary detail is discarded.

The whole three volumes of the first edition have been reproduced by the University of Chicago Press – another impressive bibliographical achievement. volume 3 carries the bibliography of Lyell's sources by Rudwick (1991), an invaluable aid to the Lyell scholar. So the *Principles* is nicely available, and the life story carefully told. Lyell's more intimate moments are caught in the *Life and Letters, and Journals of Sir Charles Lyell, Bart* edited by his sister-in-law Kathleen Lyell (1881).

Poulett Scrope (1797–1876)

George Julius Poulett Scrope and Charles Lyell were secretaries of the Geological Society of London in 1825. Scrope was interested in the volcanoes of the Auvergne region and wrote quite extensively on this topic; his *Volcanoes of Central France* was reviewed by Lyell for the journal *Quarterly Reviews*, and this review is seen as a major pioneering geological work by Lyell. This review of more than 40 pages allowed Lyell to set out his basic ideas on geology – which he went on to develop throughout his life in the successive editions of the *Principles* (Lyell 1827).

Bailey (1962, p. 67) quoted a section of Poulett's writing which he offered as a sort of mantra for Lyell's approach to geology:

The leading idea which is present in all our researches, and which accompanies every fresh observation, the sound which to the ear of the student of Nature seems continually echoes from every part of her works, is- Time! –Time! –Time!.

The concept of time is key to the works of Lyell. He establishes the importance of time. Deep time – geological time – was more or less invented by James Hutton (1726–1797), but Hutton was an incoherent apostle for his great invention; Lyell was the great prophet of time, and the *Principles of Geology* presented to the world the concept that the world was very old and that deep time extended back an almost inconceivable distance. There was plenty of time for the processes of evolution to operate.

Uniformitarianism

The term “uniformitarianism” as used in modern earth sciences has been reviewed by Romano (2015). The term is essentially now synonymous with the entire theoretical system proposed by Lyell in the *Principles*: “the present is the key to the past.” The term was coined by Whewell in 1832 to indicate a specific part of Lyell’s hypothesis, but over the years, it has become the central part of the Lyell doctrine. Time – deep time – is required in which geological processes can operate.

Darwin Correspondence Project

The Darwin Correspondence Project has set out to collect and publish all of Charles Darwin’s letters, letters to Darwin and letters by Darwin. Since Darwin was a prolific letter writer, the list of correspondents includes many notables of the time. There is, of course, a considerable section of letters to and from Lyell. Letter DCP-LETT-4149F dated 9 May 1863 from Lyell to Darwin related the events around Lyell’s conversation with Queen Victoria; the Queen wished to talk about Darwin.

Letter DCP-LETT-335; dated 26 December 1836

From Lyell to Darwin

Will you come up on Monday January 2, and come and dine with us at half-past five o’clock, or come at five, and I will go over the paper before dinner? No one dines with us but Mr and Mrs Horner and one daughter, and Mr Horner will be glad to renew his acquaintance with you.

Soon after the return of the Beagle, a close, harmonious relationship between Lyell and Darwin begins.

Principles of Geology

volume 1 of the *Principles of Geology* was published by John Murray in London in 1830. The second volume followed in 1832 and the third in 1833. By the time that Vol. 3 appeared,

second editions of Vols. 1 and 2 were already published. For the rest of his life, Lyell updated the *Principles*, and a succession of editions appeared. The 12th edition was in press at the time of Lyell’s death. It remains in print in various editions; there is a very neat one-volume edition available as a Penguin Classics.

Secord (1997, p. x), the Penguin editor, observed that *the Principles of Geology* is often read as a Victorian work, but its origins are in the Romantic era, in the religious, political, and literary history of the Regency. The first edition (published by John Murray in 1830) belongs on the shelf with De Quincey and Scott, not Dickens and Darwin. Its foundational project marks the book as part of political debates that culminated in the 1892 Reform Bill. Secord (1997, p. x) noted that many readings of the *Principles* narrow its meaning, and it is often seen solely as a precursor to Darwin’s *On the Origin of Species* (1859) – a view that would have surprised Darwin himself.

Darwin took Vols. 1 and 2 with him on The Beagle, and Vol. 3 reached him at Valparaíso in Chile. Darwin was reading about Lyell’s new enthusiasm for loess as the Beagle headed north, on the return voyage.

In the default biography of Lyell by Wilson (1972, p. 376), volume 3 is described as the first volume to contain straightforward geology:

The third and final volume of the *Principles of Geology* was in a sense the first which dealt with geology proper, or what would have been recognized as geology before Lyell began writing. In it Lyell surveyed the whole series of geological formations beginning with the most recent and proceeding back through the succession of Tertiary formations, which had been revealed in part by the work of Desnoyers, but which Lyell himself now developed far more fully and completely. (Wilson 1972, p. 376)

Antiquity of Man

The great work of Lyell’s later life was the foundation book for anthropology and prehistoric studies. Bailey (1962, p. 198) suggested that among Lyell’s achievement in his later years, the *Antiquity of Man* (1863) surely ranks highest. If it

stood along, it would place him among the foremost of scientific authors. Its scope is amazing. Bailey gives a good review of the 24 chapters. Wool (2001) pointed out Lyell's role as a forerunner of modern ecology.

Lyell and Darwin

Secord has suggested that a valuable account of the relationship between Lyell and Darwin can be found in Browne (1995). She (Browne 1995, p. 348) proposed that Darwin was the first naturalist to use Lyell's "principles" effectively, his first and, in many ways, his only fully committed disciple.

Harriet Martineau (1877, p. 268) wrote:

There were the friends Lyell and Charles Darwin, after the return of the latter from his four years' voyage round the world:- Lyell with a Scottish prudence which gave way more and more as years passed on, to his natural geniality, and to an expanding liberality and freedom of speech; and the simple, childlike, painstaking, effective Charles Darwin, who established himself presently at the head of living English naturalists.

Harriet was a good friend of Erasmus, Darwin's brother, and was well placed to observe interactions with Lyell.

Wilson (1972, p. 433) quoted this passage at the head of his chapter on Darwin and Lyell (1836–1841). He went on to say that Lyell and Darwin met frequently to discuss geology. Seldom (he claimed) can there have been a more fruitful interaction of scientific minds. Darwin had found the *Principles of Geology* an indispensable guide in interpreting the geology of South America and one which illuminated the meaning of the country for him.

The Horner Family

Lyell had several links to the Horner family. He married Mary Horner in 1832. She was the eldest daughter of Leonard and Anne Horner. In the early 1830s, the Horner family lived at Bonn. Lyell made an excursion to the Eifel region in

1831 (Smalley et al. 2016; Smalley 2017), ostensibly to look at the volcanic phenomena of that region and also to visit the Horners. During that visit he became engaged to Mary Horner. They married in 1832 and made a trip down the Rhine for their honeymoon – during which Lyell was able to observe the loess deposits and talk to Karl Caesar von Leonhard and H J Bronn, the famous mineralogists at the Heidelberg.

The Horner's fourth daughter Katherine married Lyell's brother Henry and eventually edited the *Life and Letters, and Journals of Sir Charles Lyell, Bart* – an invaluable source for all Lyell scholars (Lyell K.M. 1872).

Leonard Horner was a committed geologist (Smalley and Kels 2018) and worked with Lyell in the Eifel region. He and Lyell made a famous field trip to the crater of the Rodderberg in 1832 and investigated the loess which had been deposited in the crater. He was present at the dinner in 1836, the famous post-Beagle dinner with Darwin. Two of the diners went on to become famous geologists. Horner spent his life as a social reformer and striver for worker's rights – one of the few people mentioned by name in *Das Kapital* by Karl Marx.

Lyell's Loess Legion

Lyell's fame rests essentially on his great study of all of geology, the ongoing *Principles* project, and his association with Darwin and evolution. This great blanket of fame has to some extent obscured other aspects of his geologizing and resulted in the neglect of several geological achievements. In particular his early (1830–1836) studies on loess material and loess deposits have been unappreciated for many years. Now there is a realization that Lyell was a major loess pioneer (Lyell 1834); in fact he is one of the two major loess pioneers, sharing that honor with Karl Caesar von Leonhard (Smalley et al. 2014, 2019).

In the preface to volume 3 of the *Principles*, Lyell wrote:

In the summer of 1831 I made a geological excursion to the volcanic district of the Eifel, and on my return I determined to extend my work to three

volumes, the second of which appeared in January, 1832. The last volume has been delayed till now by many interruptions, among which I may mention a tour, in the summer of 1832, up the valley of the Rhine, when I examined the loess. (Vol. iii, p. 151)

For much of the nineteenth century, Lyell's theory of water-deposited loess was the paradigm theory for loess deposit formation. It largely held sway until replaced by Richthofen's aeolian theory in the 1880s (Smalley and Markovic 2019). Lyell identified various key workers in the field of loess studies and listed them in Vol. 3 of *Principles*. In the first edition, they were von Leonhard, Bronn, Boue, Voltz, Steininger, Merian Rozet, and Hibbert; by the fifth edition Horner (father in law) had been added, together with von Meyer and Noeggerath. Lyell was following developments in the world of loess scholarship.

Lyell and Darwin Interact

Four aspects of interaction can be identified:

1. Darwin takes Lyell's books with him on the Beagle. They provide his geological support.
2. Soon after the return, Darwin and Lyell meet for dinner, and a cooperative relationship is launched.
3. Lyell and Hooker, determined to look after Darwin's interests, arrange for the first announcement of evolution by natural selection to be a joint paper by Darwin and Alfred Russell Wallace.
4. Lyell and Darwin never reach a proper agreement on all aspects of evolution, but they are close and always reconciled.

A final word from a historian, Richard Holmes (2008, p. 454), writes that the geologist Charles Lyell began in 1830 to bring out his classic work *Principles of Geology*, which would finally use scientific evidence to reject the Biblical account of short-scale creation of the earth, as maintained by every authority from Cuvier and Paley to Buffon and Buckland. Lyell's proposal of "deep time" corresponded to the "deep space" cosmology of William Herschel. It would ultimately provide the

supportive authority for Charles Darwin, his great friend, to accept the deep time necessary for evolution by natural selection to take place.

Chase-Away Hypothesis, The

Brett Holland
California State University Sacramento,
Sacramento, CA, USA

Definition

A coevolutionary race between signals that access preexisting vulnerabilities in receiver sensory/endocrine systems in order to manipulate reproductive traits and resistance to those signals due to receiver costs.

Introduction

A long-standing question in modern evolutionary biology began with Darwin (1871), who hypothesized that “. . . ornaments of many kinds—their organs for producing vocal or instrumental music—and their glands for emitting odours. . . serv [e] only to allure or excite the female.” Why these traits succeed remains an open question. Their attractiveness may be an adaptation by the choosier sex resulting from the ornament having provided information about species identity or qualities associated with a prospective mate (e.g., genetic, resource, parasite presence) (see Andersson 1994, for an overview). Alternatively, ornament attraction may not be an adaptation. Instead, “preferences” may be pre-existing incidental sensory biases (Basolo 1990; Ryan 1990).

The chase-away hypothesis proposes that sensory biases are vulnerabilities of information processing that may be subsequently exploited by signals that induce reproductive trait changes away from the receiver’s optimum. Signals range from molecules (pheromones) to highly ornate sounds, tissues, and behaviors that may attractively stimulate the receiver. With respect to the fitness effects on receivers, these signals are no different than what is expected from brute force. Manipulated traits include the age of sexual maturity, mating frequency, and parental effort (fecundity and investment per offspring). Fitness costs select for resistance to the signals (e.g., increased cumulative stimulation required to elicit the same behavior), counter selecting increased signal magnitude. The coevolutionary race may last indefinitely and leave a trail of magnificent signals that may be of minimal value. In this model, the signal does not provide useful information to the receiver, but other models are not mutually exclusive.

Darwin-Bateman Paradigm

Most researchers agree that the source of sexual selection is described well by the Darwin-Bateman paradigm (see Parker and Birkhead 2013, for a recent introduction to sexual selection and sexual conflict). Bateman (1948) performed a simple experiment in which he assigned male and female fruit flies (*Drosophila melanogaster*) a specific number of mates. Female reproductive success increased modestly after the first mate (females can store sperm to fertilize eggs for several days), but male reproductive success increased approximately additively with each mate. Bateman proposed that female fitness was energy limited, while male fitness was fertilization limited. Trivers (1972) generalized Bateman’s analysis and identified relative parental investment (PI) as a critical organizing influence of sexual selection. PI is any investment (time, energy, etc.) in an offspring that reduces a parent’s ability to invest in other components of fitness. Sexual selection will tend to occur in proportion to the difference in PI between sexes. The fitness of

members of the greater PI sex is usually limited by their ability to convert resources into offspring, whereas the fitness of members of the lesser PI sex will tend to be limited by fertilization success. The lesser PI sex competes for the gametes of the higher PI sex. This article often uses “male” and “female” for simplicity. Because of the evolution of shared PI, or PI role reversal, it is a better predictor of reproductive strategies than sexual identity. One could also use operational sex ratio or potential rates of reproduction, rather than PI.

Life History Trade-offs

Individuals are selected to allocate investment in any activity in a way that maximizes fitness, given the innumerable trade-offs, such as between current parental investment and future capacity for parental investment. For example, when Gustafsson and Pärt (1990) randomly assigned collard flycatcher females an extra egg during their first clutch (increasing their number of eggs from approximately 5–6), their unmanipulated clutch sizes in subsequent years plummeted compared to control females who did not receive the extra egg at age one. A variety of experiments and theory produce consistent results. If life is a race, then the distance of the race determines the optimal speed. Females are selected to run a marathon, distributing their enormous parental effort optimally over time. Males are selected to manipulate females to sprint, to the extent that future offspring are likely to be sired by others.

Intersexual Conflict Over Female Optima and Sexually Antagonistic Coevolution

The foundation for the study of intersexual reproductive conflict begins with Darwin, 1871. The modern subject was reawakened by Parker (1970) and Trivers (1972). This article is concerned with intersexual conflict over female optima for reproductive traits, such as the age of sexual maturity, mating frequency, and rate and timing of maternal investment. In each case, the optimal value from a male’s fitness perspective

may differ. Such conflict can lead to sexually antagonistic coevolution (SAC), a type of arms race between other traits (e.g., pheromones and receptors) in males and females that mediate the value of the trait in question. SAC, as with that of ecological enemies, like parasites and hosts, may proceed indefinitely and occurs between traits that are produced by different genes (interlocus). For reviews, see Parker (1979), Rice and Holland (1997), Chapman et al. (2003), and Parker (2006).

SAC Over Hormonal Control of Female Reproduction

Internal fertilization and development create widespread opportunities for exploitation of maternal investment that result in costs to lifetime female fecundity and survival. Seminal fluid contains much more than sperm. Experiments with the model organism, *D. melanogaster* (a fruit fly), show that among the approximately 130 seminal fluid proteins include some that act as female hormones. For example, sex peptide (Acp70A) increases egg production, delays remating, and exacerbates the survival cost (discussed below) of mating in females (Wigby and Chapman 2005). In short, it increases male offspring production per copulation (Fricke et al. 2009) at an apparent long-term cost to female fecundity. Kuijper et al. (2006) manipulated *D. melanogaster* female remating frequency to measure dose-dependent effects of mating and found that losses in lifetime fecundity accelerated with each remating. Other polygamous insects show similar patterns. Male accessory gland secretions of the moth *Spodoptera litura* induce females to delay (polyandrous) remating and increase egg development and egg laying (Yu et al. 2014). Unfortunately, experiments do not always measure lifetime fecundity. Measuring anything less could easily lead to an opposite, incorrect conclusion about the effect of male SFPs on female fecundity in polygamous species, similar to stopping after season one of the fly catcher experiments.

Female counter evolution is sometimes harder to infer but appears likely in a number of

examples. Female *Drosophila* do not make sex peptide, which begs an explanation, given that it is a female reproductive hormone. It has been suggested that hormones might be a cue to the female that copulation is occurring and a form of assistance. This would be an invasive cue and would provide trivial energetic savings. The presence of a male on one's back and the filling of highly innervated sperm storage organs should be sufficient evidence of copulation. Further, females would have better access to information about their physiological condition and hormonal needs than would a copulating male. More likely, the ancestral state was for females to produce sex peptide, then followed a mutation, expressing sex peptide in a male's seminal fluid. The resulting increase in embryo production and delay in female remating were good for the male because his mate(s) used more of his sperm. In other words, the optimal amount of sex peptide present in a female, at mating, is greater for her mate than for her. This male-benefit trait spread. This counter selected females with decreased expression of sex peptide. SAC eventually minimized female expression of the peptide.

Another form of resistance is to decrease response to male deposited hormones. This appears to have been demonstrated by Sakaluk et al. (2006) who tested the resistance prediction of chase-away in a PI role-reversed species. *Gryllodes sigillatus* females benefit from remating because of a nutritional "gift" (spermatophylax) provided by males at copulation. Female *G. sigillatus* remate at the same interval whether or not they are allowed to eat the spermatophylax. *Acheta domesticus* is a non-spermatophylax species. When female *A. domesticus* were given the spermatophylax of male *G. sigillatus*, they accepted more sperm and took longer to remate than those not receiving the gift. The authors suggest that male *G. sigillatus* produce a substance within their spermatophylax that inhibits sexual receptivity, causing females to mate at a suboptimally low rate, and *G. sigillatus* females subsequently evolved resistance to the inhibiting substance.

In placental mammals, a parental contest over maternal investment occurs in the fetus. IGF-II is

a growth hormone that is sexually imprinted (the gene expression is reduced or silenced for one generation) in offspring, by their mothers in rodents, artiodactyls, and primates. The result is that during fetal development the only source of this growth hormone produced in the offspring (placenta) is from the paternal allele, reducing the dosage by approximately 50 %. The mannose-6-phosphate receptor is a sink for IGF-II (by binding and removing it from circulation) and is imprinted in the reverse direction in rodents and artiodactyls. That is, males turn it off in their offspring, while females do not (Burt and Trivers 2009). The logic is the same as with polygamous insects: fathers manipulate mothers to increase their investment in their shared offspring beyond what is optimal for mothers. Somewhat larger than average offspring have higher fitness and higher costs, which will be paid for by the number or quality of the mother's future offspring, sired by a different male. Females coevolved an imprinting response that moved their investment back toward their optimum.

Within each species, there is a trade-off between the age of onset of reproduction and future reproductive success through fecundity, survival, and/or offspring success. This is similar to trade-off seen with the fly catchers. This trade-off is generally inevitable or selection would favor quicker development. Pheromones within the urine of dominant, but not subordinate, male house mice can induce sexual maturation in pre-pubescent females. Prepubescent females avoid the urine of adult males. Around puberty, this avoidance stops. The above are consistent with male manipulation to hasten the sexual maturation of females that might not otherwise be reproductive during the tenure of the dominant male and behavioral resistance on the part of juvenile females to avoid the costs of prematurely entering into their reproductive phase of life.

The types coevolutionary conflicts exemplified above should be common. In general it is not possible for selection to favor males to improve female fitness through hormonal manipulations of female reproductive effort, investment per offspring, or timing of mating or sexual maturation: (1) they lack the information that females have

about their own condition; and (2) in polygamous species, the optimal *maternal* effort is higher for sires, who at the time of mating can only be selected to augment maternal effort and investment per offspring, to the extent that future offspring will be sired by other males. Males will inevitably be screened for traits that turn females into reproductive sprinters (i.e., maximize short term reproductive effort), and females will counter-evolve adaptations to minimize the manipulation and cost to their fitness.

Costs of Mating and Collateral Damage

The act of copulation has a number of substantial, direct costs to both sexes. STDs and lost energy and time are ubiquitous, and increased exposure to predation is common. In species with internal fertilization and polyandry, the perpetual coevolution among male reproductive traits will also generate collateral costs for females (Arnqvist and Rowe 2013). For example, SFPs appear to reduce female survival in a dose-dependent manner (Chapman et al. 1995) as a byproduct of sperm competition (Parker 1970). Sperm competition has selected proteins that displace any previous males' sperm and protect focal sperm from such displacement by any future seminal fluid. When a female *D. melanogaster* remates, the seminal fluid of the new mate displaces most of the stored sperm (Harshman and Prout 1994). The SFP Acp62F is a protease inhibitor that substantially reduces displacement of the focal male sperm by subsequent males' seminal fluid (Mueller et al. 2008). About 10 % of this deposited protein enters the female hemolymph, whereby it appears to reduce lifespan (Lung et al. 2002). Acp70A is also toxic in *D. melanogaster* (Wigby and Chapman 2005). Toxic SFPs have been found in two seed beetles, *Acanthoscelides obtectus* and *Callosobruchus chinensis* (Yamane et al. 2015). Seminal fluid of the moth *Spodoptera litura* also decreases female lifespan (Yu et al. 2014). The toxicity is not immediate, as that would be counterproductive for the inseminating male. The toxicity works more like an acceleration of female senescence.

In polygamous species, once a male's sperm are displaced natural selection cannot favor him to protect his former mate from collateral damage. Female adaptations may interfere with the original male adaptation, or not. However, the main point is that mating is costly and that internal fertilization creates additional costs for females. The perpetual arm's races among SFPs will sometimes generate collateral costs for females. In principle, females may recoup fitness through sons that have these same traits that reduced maternal survival. There is little theoretical support for this hypothesis (Paker 2006). In an experiment that measured female fitness and offspring fitness, the direct costs of conflict greatly outweighed the benefits in offspring (Orteiza et al. 2005).

Conflict Over Mating Frequency

The lesser PI sex generally benefits more from polygamous mating, while internal fertilization increases cost for females (e.g., hormonal manipulations and survival, discussed above). Both the benefits and costs generally favor a higher optimal polygamous mating frequency in males. Therefore, there will commonly be a conflict over mating frequency in polygamous species because it is a joint behavior with sex-specific optima. This does not imply that females cannot benefit from polyandry, as described below.

D. melanogaster has been the focus of much of the work on mating. It is a polygamous species with substantial courtship, and males provide no measurable nongenetic resources to females. Courtship throughout Drosophilids is complex, consisting of wing-song, touch, and pheromones. Wing-song in *D. melanogaster* is a pronounced display in which the male extends one wing toward a female and beats it in a species-specific rhythm while he walks in a semicircle in front of her. Males that provide altered song, or no song, suffer substantially lower mating success which is partially restored by playing an artificial song. Courtship is also stressful to females, reducing longevity (Partridge and Fowler 1990). Linder and Rice (2005) found that genetic variation for female susceptibility to all forms of male harm

comprises 17 % of the total genetic variation for female fitness. Variation in female ability to limit remating in response to persistent courtship was a major component of female susceptibility. The cost of mating to females rises nonlinearly with copulation frequency (Kuijper et al. 2006). The above findings do not appear to be a laboratory artifact. Observations in nature indicate that female mating frequencies are similar, if not identical, to those observed in laboratories (Kuijper and Morrow 2009) and mating decreases female lifespan in a variety of Diptera and Orthoptera insects (Simmons 2001).

Experiments in which populations were made monogamous over evolutionary time indicate that the load on female fitness specifically due to sexually selected conflict is substantial. In populations of fruit flies maintained under experimentally enforced monogamy with random mate assignment, and control populations that retained the opportunity for sexual selection, males evolved to court less and cause lower mortality per mating. Females evolved reduced defenses to male harm, implying that ancestral females possessed adaptations to resist male harm. Within 45 generations, these populations produced approximately 20 % more offspring per generation than controls, which is a substantial peace dividend (Holland and Rice 1999).

The above is meant to illustrate important points, not exhaust possibilities. There can also be benefits to polyandry: sterility, low gamete levels, genetic compatibility, and increasing the genetic variation among offspring are all important (and also important to males). Sometimes females benefit from remating because it generates protection from the current mate or otherwise reduces harassment, or they may be able “trade-up” to a mate of higher quality (see Parker and Birkhead 2013). The critical issue is relative optima. The cost:benefit ratio tends to favor a higher optimal mating frequency in the lesser PI sex.

In summary, there are innumerable conflicts that arise as a consequence of polygamy. Across taxa, males possess traits that in various ways manipulate female reproductive physiology and behavior and/or reduce survival, at a cost to

female fitness. Females possess adaptations to resist male manipulations. Endocrine reproductive manipulation and female resistance are one example of a coevolutionary struggle. Sensory systems may also be hacked.

Sensory Bias

The frog *Physalaemus pustulosus* includes chucks in its male mating calls and females are attracted to these chucks. This same attraction exists in females from a different group in which the males lack the chuck in their vocalization. Phylogenetic analysis indicates that the female attraction predates the male display (Ryan and Rand 1993). In swordtail fish, including *Xiphophorus helleri*, males possess ornamental extensions of the caudal fin (“swords”) which are sexually attractive to females (Basolo 1990). In a sister group, including *Priapella olmecae*, swords are absent. When artificial swords were surgically attached to males of the swordless species, females of that species were attracted to them (Sinervo and Basolo 1996). As with the frogs, phylogenetic evidence indicates that the female attraction predates the evolution of the male display. This is inconsistent with benefits models of sexual selection, which predict that the preferences are adaptive *responses* to the fitness gains associated with the display. Therefore, benefits models do not predict sister taxa with preferences for displays that they have never had a chance to benefit from.

Resistance to Sensory Bias

Using larger males from a closely related species, Ryan and Wagner (1987) demonstrated strong sexual selection by female pigmy swordtail fish, for larger male size. At that time, large body size was not known to occur in any natural pigmy populations. In 1988, large males were discovered in three adjacent, natural populations of the pigmy swordtail. The frequency of large males varied from common to rare along a distance gradient, possibly indicating the spread of large

males from a source population to two downstream populations. In 1988, female preference for large body size was found only in the population where large males were rare. This pattern was also observed in 1993, but the degree of preference for large male body size had diminished further. Both the absence of female preference in the two populations where large males were common and the diminishing preference in the population where large males were rare suggest that female resistance, rather than preference, was evolving for large body size.

McClintock and Uetz (1996) studied two species of wolf spiders. Only one species has evolved tufts of bristles on the forelegs. Phylogenetic analysis indicates that the tufts are a derived character (evolved after divergence from the lineage leading to the tuftless species). Females watched videos of courting males and were graded for sexual receptivity behavior. Manipulation of video images was used to add, remove, or enlarge the tufts on the same males (i.e., every other aspect of the male's appearance was identical). Sexual receptivity in females of the tufted species (*Schizocosa ocreata*) was unaffected (or so small as to be statistically indiscernible) by the presence, absence, or enlargement of tufts. However, in the tuftless species (*S. rovnneri*), the addition of tufts more than doubled the acceptance rate of females to their own, naturally tuftless males. In short, females were attracted to a male ornament more strongly when they lack an evolutionary history with it, indicating that females from the tufted species had evolved resistance to, rather than preference for, this sexual stimulant.

Alex Basolo (1998) also measured the strength of female preference for swords in *X. helleri* and the artificially sworded *P. olmaceae* (see above). Female preference was substantially stronger in the genus that has not evolved swords. Assuming the level of attraction to swords in the swordless species is representative of the primitive state in the sworded species, the strength of female preference for swords has declined in the sworded species, presumably following the evolution male exploitation of the female sensory bias.

Conclusion

The above findings suggest a conflict-based model for the evolution of male signals: (1) sensory and endocrine vulnerabilities in receivers, favor (2) mutations that create (and subsequently elaborate) signals that manipulate those vulnerabilities, resulting in (3) increased mating and fertilization success, and manipulation of maternal effort, and (4) increased cost in receivers due to fitness lost through mating too often/seldom, too early after sexual maturity, etc., and fecundity schedules (e.g., excessive rate of reproduction or investment per offspring), which in turn (5) counter-selects receivers who are relatively resistant to the novel (or elaborated) signals. Steps 2–5 recur in a coevolutionary tug of war between signals and receivers (Holland and Rice 1998).

Chase-away makes two predictions that distinguish it from other models of sexual selection: (1) signals reduce the net fitness of the receiver. For example, if there is variation in receiving sex for mating frequency, it predicts that individuals with below average attraction to the signal will also have below average mating frequencies and will have greater fitness through *lifetime* fecundity (barring PI role reversal, as with *G. sigillatus*), and (2) the evolution of decreased sensitivity/attraction for a signal following its evolution (Holland and Rice 1998; Sakaluk et al. 2006). Reviewed above are examples consistent with these predictions for hormonal, visual, and auditory stimuli. Counter examples were not found.

The opportunities for chase-away are broader than discussed in this article, which focused on PI and mating in polygamous species. For example, chase-away can occur in monogamous systems over mate choice. Once paired, conflict between monogamous mates ceases (assuming true life-long monogamy). If there is remating, for example, after a mate dies, then natural selection sees polygamy, regardless of what we may call it. See Rice and Holland (1997, 1999) and Holland and Rice (1998) for a broader discussion of SAC between genes that mediate intersexual reproductive behavior.

Cheater Detection

Tess Langfield
University of Cambridge, Cambridge, UK

Definition

The ability to detect non-reciprocators in social exchange scenarios, in which a cheater obtains a

benefit, without satisfying the condition given by the benefit provider

Introduction

Cheater detection, or the ability to detect individuals cheating in social exchange scenarios, is often seen as a branch of evolutionary psychology that shows great promise. The social exchange algorithm, or social contract theory, was developed in Leda Cosmides' now seminal paper (Cosmides 1989) and has generated much interest from those who generally support evolutionary reasoning, those who ardently oppose it, and all those in between. For Cosmides, and others (e.g., Cosmides and Tooby 1992), the enhanced ability of detecting cheaters in logical reasoning tasks, relative to more general reasoning abilities, represents evidence of an evolutionary selection on cognition and, more specifically, of an evolved module specialized for the purpose of detecting cheaters. Although some disagree with this implication, many would accept that, more broadly, this research program has succeeded in providing clear, testable hypotheses, as well as a prespecified paradigm to test them.

Cheater Detection and Social Exchange

Within evolutionary psychology, it is generally proposed that the mind is made up of mechanisms or “adaptations” that were “designed” by natural selection to solve recurrent problems faced by our ancestors in evolutionary history. One such problem likely involved social exchange or cooperation with others to allow for mutual fitness benefits. It is helpful to imagine the following conditional, typical of a social exchange scenario: “If you accept Benefit B from me, you must satisfy Requirement R.” Traits that led to cheating the system, that is, taking Benefit B and gaining the associated fitness benefits, without satisfying Requirement R, would have been selected for, as they allowed the cheater fitness benefits. As a result, the ability to *detect* these cheaters would

also have evolved over time. In essence, for the very act of cooperation to exist, without it being eradicated due to excessive cheating of the system, we must have developed the cognitive capacity to detect non-reciprocators in these scenarios. Based on a series of studies, Cosmides (1989) and Cosmides and Tooby (1992) have suggested that the problem of social exchange scenarios and the possibility of non-reciprocation have, through natural selection, led to the evolution of an automatic, domain-specific cheater-detection module, which is present and observable in human cognition today.

The Wason Card Selection Task

The paradigm that Cosmides (1989) used to support her social contract theory and the existence of a cheater-detection module was the Wason card selection task (Wason 1966). Initially developed to test conditional reasoning, the task involves detecting possible violations of a statement in the form “If P, then Q.” Participants are required to select which of four cards could, in theory, violate this rule, when turned to reveal the other side of the card (see Fig. 1a for an abstract example). The visible sides of the cards show instances of P, not-P, Q, and not-Q (although they are not labelled as such), and the *only* violations of the “If P, then Q” rule could be gleaned from turning over P (to show not-Q) and not-Q (to show P). Generally, performance is poor on the descriptive and abstract versions of this task, with only around 10–25% of participants identifying the appropriate cards to turn (e.g., Wason 1966; Cosmides 1989).

Crucially, when the task was couched in terms of social contracts, Cosmides (1989) found content-related performance facilitation. When presented in the form “if you accept a Benefit B, you must satisfy Requirement R,” reflecting a social exchange scenario, accuracy at detecting violations increased to around 65–80% (Cosmides 1989; Cosmides and Tooby 1992; see Fig. 1b for generic form of social contract task). An actual example of this conditional given in a social exchange context might be the following

rule: “If you use my car, you must pay for petrol,” such that P = using my car and Q = paying for petrol. To detect a cheater in this scenario, one must ascertain whether someone who used the car (P) did not pay for petrol (not-Q) and whether someone who did not pay for petrol (not-Q) used the car (P).

Supporting Evidence

Aside from performance facilitation in cheater-detection contexts already discussed (e.g., Cosmides 1989; Cosmides and Tooby 1992), further support for this purported domain-specific mental module can be derived from evidence of selective impairment in cheater-detection reasoning, relative to more general reasoning abilities. Stone et al. (2002) found that while control subjects performed similarly on both tasks, patient RM, who had extensive bilateral limbic system damage, performed much worse on a Wason card selection task involving social contract rules (“If you take benefit B, then you must satisfy requirement R”), relative to a problem regarding precaution rules (“If you engage in hazardous activity X, you must take precaution Y”). This selective impairment for cheater detection provides support for the existence of an independent, specified mechanism that drives performance and is less consistent with a domain-general mechanism supporting reasoning.

Cross-culturally, there appears to be similar performance facilitation in social contract scenarios, relative to general task performance, as found in a group of nonliterate horticulturalists in the Amazon (Sugiyama et al. 2002). Furthermore, van Lier et al. (2013) found that enhanced performance for cheater detection did not depend on age or cognitive capacity and that requiring participants to complete another task simultaneously, thus placing a burden on cognitive resources, had no impact on performance. This suggests automaticity to the mechanism, which is consistent with the modular view of the human mind advocated by many evolutionary psychologists, including Cosmides (1989) and others (e.g., Cosmides and Tooby 1992).

Cheater Detection, Fig. 1 (a) Abstract, descriptive example of the task, given the conditional rule: “If there is a vowel on one side (P), there will be in even number on the other side (Q).” Given that detecting violations of “If P, then Q” always relies on turning cards “P” and “not- Q,”

the correct items to turn would be E and 7. (b) Generic social contract version of the task, given the rule: “If you take Benefit B (P), you must satisfy Requirement R” (Q). The correct items to turn would be Took Benefit B (P) and Did Not Satisfy Requirement R (not-Q)

Controversies

Research on cheater-detection and social exchange scenarios has generated much debate within the scholarly community. One example comes from a study offering an alternative explanation for the findings. Sperber et al. (1995) argued that people generally use intuitions to solve the Wason card selection task and that there were differences in the accessibility and salience of these intuitions, depending on the conditional used. Crucially, for many of the cheater-detection conditionals, “P and not-Q” was easier to represent, more salient, and more relevant than “P and Q,” which, according to their relevance theory, accounted for correct card selection (“P” and “not-Q”).

Others have argued that the ability to detect cheaters could have developed through learning and that there is no particular reason why we must infer an innate, domain-specific module to account for content-related performance facilitation effects (Gray et al. 2003). These authors suggest that functional responses, that exist without awareness and occur automatically, need not be the result of an evolved module. To give their example: when riding a bicycle, if one begins tilting over to one side, one is able to right oneself. This ability is automatic, and we are typically not

aware of how we do it. Indeed, as Gray and colleagues suggest, many people give an incorrect response as to what they would do when in this predicament. However, there is no reason to assume that this automatic, functional response is the result of an innate, evolved “bike-riding module.” Thus, Gray and colleagues argue there is no particular reason to believe that the ability to detect cheaters relies on an evolved mental module, rather than simple learning mechanisms.

Conclusion

Research on cheater detection is often touted as a branch of evolutionary psychology that has delivered real insight into human cognition. Since the proposal of the social contract theory, there have been many studies demonstrating stark differences in performance on reasoning tasks, depending on the context in which the conditionals are placed. Specifically, detecting violations of conditional rules is easier, reflected in better task performance, when the scenario is given in terms of identifying cheaters of social exchange. For Cosmides (1989), this evidence is most parsimoniously explained by appealing to a cheater-detection module, which has evolved

through natural selection as a solution to the inherent problem our ancestors faced with social exchange scenarios. However, despite mounting evidence for cheater detection, the mere presence of this effect is not enough to convince some scholars of the underlying cognitive architecture that drives performance on the task. Regardless, the evidence on cheater detection has encouraged a range of researchers to debate what was previously assumed true, a feat that will surely contribute to our developing understanding of human cognition and the mechanisms that underlie it.

Cheater Detection Adaptations

Anna Wysocki
Oakland University,
Rochester, MI, USA

Definitions

Cheater detection adaptations are evolved mechanisms that facilitate the identification and avoidance of cheaters.

Introduction

Cooperation has evolved in humans as a means to increase survival within groups. However, within cooperative interactions, there is always the possibility of exploitation wherein one party would receive the benefits of a cooperative social exchange but fail to reciprocate (Axelrod and Hamilton 1981; Trivers 1972). In these cases, cooperation fails to be adaptive and instead poses significant costs to the exploited individual. Given the costs, there may be cheating detection mechanisms functioning to minimize the likelihood of an individual being victim to a cheater (Cosmides 1989; Cosmides and Tooby 1992). These mechanisms may include a heightened ability to recognize and recall the faces of cheaters, and the same heightened ability to remember previous interactions with cheaters as a means to allow individuals to identify, recognize, and avoid potential cheaters (Cosmides and Tooby 2005).

Evidence for Cheating Detection Adaptations

Much of the research on cheating detection mechanisms has focused on assessing whether memory is heightened for faces that have been labeled as a cheater. Initially, studies found that recognition memory (i.e., the ability to assess whether you

have seen a person before) improved when identifying cheaters (Oda 1997; Mealey et al. 1996). However, recent studies have failed to replicate this finding (Barclay and Lalumière 2006; Mehl and Buchner 2008) calling into question its validity. However, further research suggests that although recognition memory may not increase with respect to cheaters, source memory may increase. In other words, individuals are better able to remember where or how they know someone from when the target has been labeled a cheater (Buchner et al. 2009). There is also evidence that individuals contain some ability to identify cheaters through facial photographs (i.e., cheater detection rather than cheater recognition; Verplaetse et al. 2007; Yamagishi et al. 2003). For example, there was a positive association between participants' ratings of an individual's honesty after looking at a picture of their face and that (pictured) individual's report of their willingness to deceive (Bond et al. 1994).

Although the previous studies are considered as support for the existence of cheater detection mechanisms, there are researchers who argue that these findings could be attributed to a general cost-avoidance mechanism rather than a specific cheater detection mechanism (Sperber et al. 1995). Alternatively, the increased source memory for cheaters may be due to heightened memory for potentially costly events or for events that violate social norms. Additionally, given that negative information is remembered better than positive information (Kensinger 2007), increased memory for cheaters may be due to cheating being perceived as a negative behavior (for further discussion on alternative explanations, see Bell and Buchner 2012).

Conclusion

In summary, evidence suggests that individuals have an increased source memory for cheaters and that individuals have at least some ability to discriminate between cheaters and noncheaters based on facial photographs. However, there is disagreement on whether these findings are due

to a specific cheating detection mechanism or due to a more general mechanism such as a cost-avoidance mechanism. Future research is needed in order to fully assess which theory has greater validity.

Definition

Child abuse is defined as aggression or negligence toward a minor (typically by an older individual, e.g., parent/guardian, caregiver, family member) that inflicts harm on the child or jeopardizes the child's well-being. Bullying is the repeated intentional use of aggression to harm a peer(s) and is characterized by an imbalance of power in which the bully has more power (e.g., more physical strength or size, higher social standing, more social capital) than the target.

Introduction

Aggression is broadly defined as behavior intended to cause harm, injury, or pain to others through physical, verbal, or indirect means. Bullying and child abuse are two forms of aggression in which the perpetrator has more power than the target. Child abuse can occur in a variety of ways such as physical, verbal, emotional, or sexual abuse. The power discrepancy in child abuse is generally implicit in the age difference between the perpetrator (i.e., adult) and target (i.e., child) in which the older perpetrator holds more power and control than the target. Bullying also occurs in different forms such as overt/physical, verbal, indirect/relational, or cyber aggression. The power discrepancy between peers in bullying is

most commonly due to physical size differences (e.g., the target being smaller in stature or weaker) or position in the social hierarchy (e.g., the target having less social capital/influence).

Forms and Prevalence

Bullying. Bullying occurs in several different forms including overt/physical (e.g., hitting, ruining possessions), verbal (e.g., name calling), indirect/relational (e.g., ostracism/exclusion), and cyber/electronic (e.g., texting, social media) aggression. Approximately 30% of youth self-reported being involved in bullying as either a bully, the target of bullying, bully victims, or bystanders (e.g., actively or passively supporting the bully or defending the victim). Although rates of bullying are highest during adolescence, bullying occurs across the lifespan starting as early as preschool and kindergarten to elementary, middle, and high school and continues into universities and the workplace in emerging adulthood, adulthood, and nursing homes during older adulthood (e.g., Rex-Lear et al. 2012; Vlachou et al. 2011). In their meta-analysis of 80 studies, Modecki et al. (2014) concluded that adolescents were twice as likely to engage in more traditional forms of bullying (e.g., physical, verbal, relational) compared to cyberbullying; however, cyberbullying was significantly correlated with traditional forms of bullying.

Child Abuse. Child abuse can also occur in a variety of forms that includes physical (e.g., hitting, punching), verbal (e.g., demeaning, hurtful comments), emotional/psychological (e.g., humiliation), neglect (e.g., abandonment, malnutrition), and sexual (e.g., rape) abuse. Physical abuse is the most commonly experienced form of child abuse that adults retrospectively report followed by sexual abuse and emotional abuse (e.g., Afifi et al. 2015; May-Chahal and Cawson 2005). May-Chahal and Cawson (2005) also found that children are at a higher risk for experiencing physical and emotional abuse in their homes, whereas out of the home, they are at higher risk for sexual abuse. However, less than 10% of adults who reported experiencing child abuse

recall having contact with child protective services/organizations (e.g., Afifi et al. 2015); people who reported experiencing physical abuse, sexual abuse, and exposure to intimate partner violence were most likely to have had contact with child protection organizations (rather than experiencing a single or two types of abuse).

Risk Factors

Bullying. People engage in bullying for a number of reasons. The stereotypical perception of a bully is of someone who is large in stature, has low self-esteem, and does not socially fit in with peers. This type of bully is typically physically aggressive rather than relationally aggressive and tends to be reactive and impulsive (i.e., likely to use hostile aggression). In contrast, according to Vaillancourt et al. (2010), the Machiavellian bully is an individual with strong social skills and high self-esteem who is well regarded and respected by peers and adults. The Machiavellian bully uses peer aggression in a calculated, manipulative way in order to gain benefits and to gain or retain power; this type of bully is often socially skilled and tends to have a high position in the social hierarchy. The Machiavellian bully is typically relationally aggressive rather than physically aggressive; he/she is likely to use peer aggression as a way of achieving personal gains (i.e., likely to use instrumental aggression).

Despite the research being correlational in nature, researchers have identified several risk factors associated with people who bully others. For example, youth nominated as bullies by peers were more aggressive, exhibited high motor functioning, and lower anxiety during preschool (as retrospectively reported by parents); youth peer nominated as bullies were also likely to come from families of lower socioeconomic status and have parents with more externalizing problems (i.e., substance abuse and antisocial behavior; Jansen et al. 2011). In addition, witnessing domestic violence during early childhood and experiencing child maltreatment predicted being identified as a bully. Boys are also significantly more likely than girls to be identified as a bully;

however, this sex difference does not appear to hold when examining relational aggression.

Child Abuse. Several risk factors predict whether an individual will abuse children. Parents who have been diagnosed with a mental health problem (e.g., psychiatric disorder, substance use disorder, or developmental disorder) are at a higher risk of abusing their children than those without mental disorders. In addition, parents who experienced child maltreatment during their own childhood, were placed in foster care, or experienced intimate partner violence are more likely to maltreat their children. Additional risk factors of perpetrating child abuse include living in poverty and having limited access to early childhood education and social services. In addition, babies who are considered fussy babies are at higher risk for being maltreated than babies with an easy temperament.

Effects on Target

Bullying. There are a host of negative mental and physical health ramifications on people who are bullied by their peers. For example, people who have been bullied are more likely to exhibit internalized problems such as depression, anxiety, loneliness, symptoms of post-traumatic stress disorder, and suicidal thoughts, as well as externalizing problems such as rule breaking, aggression, and substance use/abuse compared to people who have not been bullied. In addition to mental health problems, youth who are bullied are more likely to have physical health symptoms such as mouth sore, sore throats, stomachaches, and fatigue than youth who are not bullied. College students who are bullied are more likely to have bone and joint problems and have been told by doctors that they are at risk for heart problems compared to students who have not been bullied. This increased risk of physical health problems may be due to differences in physiological functioning; people who have been bullied tend to have lower morning salivary cortisol levels and an overall flatter diurnal cortisol pattern compared to people who have not been bullied. Children who are bullied in early elementary school are at higher

risk to be bullied later in elementary, middle, and high school than children who are not bullied in early elementary school.

Child Abuse. Children who experience child abuse are at a higher risk for mood and anxiety disorders such as bipolar disorders, anxiety disorder, phobias, and post-traumatic stress disorder than children who were not abused. Children who experience abuse are also at higher risk of developing behavioral and emotional problems such as emotional instability, depression, suicidal thoughts and attempts, and a tendency to be aggressive or violent than children not abused (e.g., Stirling et al. 2007). Experiencing child abuse can alter future stress responses (e.g., heightened sensitivity). Children who have been abused or neglected (especially children who were physically abused) were more likely to have arrest records for delinquency and crime as adolescents and adults compared to non-abused children. Maltreated children are also at higher risk of being injured by intimate partner violence in adulthood, whereas neglected children were more likely to be the perpetrator of intimate partner violence in adulthood (Widom et al. 2014).

Similar to the effects of being bullied, there is evidence that early trauma may affect neurological and physiological functioning. For example, according to Fonzo et al. (2016), adults who were emotionally maltreated as children displayed different brain activities (e.g., more amygdala activity and less right dorsolateral prefrontal activity) when viewing faces displaying fear or anger compared to adults who were not emotionally maltreated. In addition, adults who experienced abuse as children had altered salivary cortisol levels (both daily diurnal patterns and in response to an acute stress test). These physiological differences may increase people's risk of mental health problems such as depression and anxiety.

Conclusion

Being the target of others' aggression, whether by peers (i.e., bullying) or adults/caregivers (i.e., child abuse), can have lasting negative impacts on youth's development and health. As discussed

above, both bullying and child abuse are associated with more mental (e.g., depression, anxiety, suicidal thoughts, psychological disorders) and physical (e.g., stomachaches, fatigue) health problems. In addition to increased health problems, people who experience child abuse or who are bullied are at higher risk of developing behavioral and emotional problems compared to people who do not experience such trauma. Moreover, there is evidence that these negative outcomes may be explained by physiological differences (e.g., salivary cortisol, brain activity) among people who experience bullying and child maltreatment. Perpetrators of child abuse or bullying may have been victimized during their childhood or experience mental health problems; environmental characteristics (e.g., living in poverty, resources available in the community) are also risk factors in whether abuse will occur. Both child abuse and bullying are traumas that have long-term negative impacts.

Child Care

Ezgi Sakman

Department of Psychology, Cornell University,
Ithaca, NY, USA

Department of Psychology, Bilkent University,
Ankara, Turkey

Synonyms

Alloparenting; Day care; Early care and education; Non-parental child care

Definition

Child care refers to any arrangement for taking care of young children when they are not with their parents, who may be working or studying.

Introduction

Before children start elementary school (or kindergarten), they typically require some form of day care by another adult if their primary caregivers are working or studying outside of the home. The settings of child care are rather diverse, ranging from informal arrangements of taking care of the child at the home setting by a relative, a neighbor, or a nanny to formal, center-based solutions offered by preschools, nursery schools, or day care centers employing providers with relevant education and training. While informal child care arrangements typically do not have set standards for their execution, professional child care centers usually group children by age and are required to meet certain criteria, such as child-to-provider ratio and health and safety standards. In the following sections, first evolutionary accounts of child care will be offered, then the need for child care in the contemporary context will be discussed, and finally the consequences of child care will be elaborated.

Evolutionary Accounts of Child Care

Child care has been an evolutionary need as the altricial nature of human infant necessitates rather laborious care for a long period of time due to extended childhood and adolescence in humans. This made raising a human offspring on one's own too costly and necessitated collective caregiving, resulting in humans being an exception to the mammalian norm that offsprings are primarily taken care of by the biological mother. In humans, it is typical for adults other than the biological parents to offer care for young children. These adults can be genetically related to the child, such as grandparents or members of the extended family

(e.g., aunts, uncles); or they can be non-kin, such as friends, neighbors, or professional caregivers. The care offered by these adults, termed *alloparents*, is argued to have evolved because this collective care increased the chances of survival of the immature child and their development into reproductive age (Hrdy 2009). Access to alloparenting has indeed been reliably linked to greater child survival (Sear and Mace 2008). Alloparenting is also an evolved solution to the trade-off between provisioning and child care parents face. Biological parents can rely on alloparents to take care of their children, while they seek access to resources (e.g., hunting/gathering or agriculture in traditional societies, higher education or work in modern life). This cooperative childrearing system is seen in both traditional and modern cultures (Sear and Mace 2008).

The most common form of alloparenting is child care offered by grandparents, particularly maternal grandmothers, which is theorized to have evolved to increase inclusive fitness through making sure one's genes survive into the generation following their own offspring's. The findings showing grandparenting effort is highest among maternal grandmothers, followed by maternal grandfathers, paternal grandmothers, and finally paternal grandfathers, provide support for this conjecture, indicating grandparenting effort decreases with risk of paternity uncertainty, hence potential for fitness (Euler 2011). The extended period of life after reproductive years in human females is also argued to be another adaptation evolved to increase inclusive fitness through helping offspring raise their offspring, also known as *the grandmother hypothesis* (Hawkes et al. 1998; Hrdy 2009).

Child care offered by non-kin, such as friends, neighbors, or professional caregivers, is also very common in both traditional and modern societies. This type of non-kin child care also has adaptive advantages, this time within a reciprocity framework, where these individuals gain access to either material resources, in the case of professional caregivers, or social resources in the form of receiving care for their offspring when they need it, in the case of friends and neighbors.

Need for Child Care in the Contemporary Context

In the modern context, child care serves two main functions: enabling parental employment and supporting school readiness in children. With increasing maternal employment and higher education pursuits of parents, child care has become one of the most important needs of contemporary life. Parents, especially mothers, with access to reliable and high-quality child care can contribute to the workforce more easily and efficiently, which has significant positive downstream consequences for economic welfare and gender equality. Day care also prepares the child socially and cognitively for primary school by providing a stimulating environment, therefore enabling a smoother transition to formal education with higher success. This growing need for child care has resulted in a rapid increase in the number of institutions that offer professional day care services all around the world. These center-based day care options are typically costly, sometimes even costlier than other family expenses such as food or rent, so family income becomes an important factor in whether children can have access to this form of caregiving.

Consequences of Child Care

At the earlier years of the expansion of child care services, there was a widespread concern that receiving care from someone else than the mother could lead the child to develop insecure attachment to their mother and hence experience negative downstream consequences in their development. This concern led to empirical research, chiefly carried out by the National Institute of Child Health and Human Development (NICHD) Child Care Research Network. The NICHD Study of Early Child Care and Youth Development, which was launched in the early 1990s, investigated thousands of children in day care over years and reached exciting results. One of the main findings of the study was that as compared to early child care experience, parenting is as a stronger and more consistent predictor

of children's developmental outcomes and non-parental care is not associated with the quality of infant-mother attachment. Yet, long hours of center-based day care were found to be moderately related with increased problem behaviors, especially in middle-income children. Higher-quality child care predicted higher cognitive (e.g., vocabulary, reading, mathematics) and social competence that seem to be maintained into adolescence and adulthood. Higher educational attainment and improved economic outcomes have also been linked with high-quality child care. The child-to-provider ratio has been identified as a crucial factor in determining the quality of care offered in day care centers, with lower ratios predicting better outcomes. The interested reader is directed to the papers by Belsky and colleagues (2007), Dearing et al. (2009), and Vandell and colleagues (2010) for the results of this large-scale multistate study and reviews of other studies investigating the links between child care and developmental outcomes.

It is worth noting that higher-quality child care seems to benefit children living in low-income families the most (e.g., Havnes and Mogstad 2015). Low-income children who has had the chance to attend high-quality day care show better academic outcomes, higher employment, and less criminal behavior as teenagers and young adults (e.g., Schweinhart et al. 1986). Higher-quality child care is thought to act as a buffer to dampen the negative effects of growing up in an otherwise impoverished environment through better access to resources; higher cognitive, social, and emotional stimulation; and social ties with providers and friends. There is even evidence to suggest that high-quality child care acts as a buffer against problem behavior for children with mothers who report depressive symptoms – typical of stressful parenting environments (Charrois et al. 2017). Hence, early education has been identified as one of the most cost-effective and efficient ways of enhancing the developmental outcomes of children from impoverished backgrounds. This led to increased governmental efforts in providing accessible child care to low-income families in many countries, such as the United Kingdom and Italy. The most well-known example of such

efforts is the federally funded Head Start Program in the United States. The benefits of the Head Start Program seem to be most prevalent in high-risk populations (e.g., foster children, children from families with lower levels of education), yet the effects are attenuated when the children move to public elementary schools, which probably have fewer resources.

Conclusion

Child care, an evolutionary necessity imposed on humans by the altricial nature of human infants, is playing an increasingly central role in child development with more parents joining the workforce and/or pursuing advanced education. Research shows that child care is not at all harmful for optimal child development – to the contrary, it contributes to positive outcomes, but only when it reaches a certain level of quality. So, organized efforts toward making high-quality child care affordable and accessible are crucial in achieving both optimal child development and a more productive labor force.

Child Custody

Divorce occurs in both industrialized and non-industrialized cultures (Anderson 2011). Following this dissolution, the decision of who receives custody may become an issue for parents and the

state. In industrialized nations, women are much more likely to be granted full custody of children (Anderson 2011). For example, in the United States, one study found that the majority of single-parent households (84%) were headed by mothers (Grall 2007). In some non-industrialized nations, the same child custody pattern occurs as well. For example, in the Hadza, a hunter-gatherer tribe, divorce is common, and when it occurs, the majority of the children live with the mother (Marlowe 2010). However, data from across 45 societies found 17.8% and 20.0% of the time children resided with mothers and fathers, respectively. From this same sample, 53.3% of those who received custody of the children were granted custody based upon a variety of factors (Frayser 1985). Factors that may play a role in who receives custody could be parental death, the role of kin as guardians, the age of the children of the parents who decide to divorce, the role that stepfamilies may play, the possibility of child abuse, and the biases inherent in the court system.

From an evolutionary theory perspective, it is not surprising that mothers are granted custody more often. Mothers more often receive custody due to relative parental investment. The relative time one parent may invest begins before conception given the vast difference in sex cells (Trivers 1972). Furthermore, given that fertilization and gestation are internal and that breastfeeding typically occurs after birth for 3–4 years, there is a greater duration of parental investment for women than for men. If a child needs to continuously breastfeed, it would be adaptive for the child to spend much more time with his or her mother than with his or her father. Due to the adaptive nature of spending more time with the mother, cross-cultural research shows that fathers do not spend the same amount of time or care for children to the same capacity that mothers do (Geary 2000). Additionally, women may also be more likely to receive custody because they are better able than men on average to control their emotional responses. Women on average can delay their own gratification and control aggression better than men (Kochanska et al. 1996), which are adaptive skills to have when raising offspring.

Taken together, these differences in parental investment and in women's behavior may contribute to why mothers may be awarded custody more often.

However, while women may receive custody more often due to the extended childhood of humans (Bjorklund and Shackelford 1999), fathers may also receive partial custody. This can also be explained from an evolutionary perspective. Men can engage in a flexible mating strategy in order to increase their own fitness by investing time in a limited amount of offspring (Buss and Schmitt 1993). Therefore in some cases, men may want to increase their fitness by caring for their child.

To conclude, while using evolutionary theory to explain child custody is useful in understanding typical scenarios, a further examination of other factors must be considered in real-life custody situations to determine the best outcome for children.

Definition

Child mortality, also known as under-5 mortality, refers to the deaths of children under the age of 5 and is often reported as the number of deaths per 1,000 live births.

Introduction

Child mortality, also known as under-5 mortality, refers to the deaths of children under the age of 5 and is often reported as the number of deaths per 1,000 live births. A special case of child mortality is infant mortality, which includes all deaths prior to 1 year of age. The majority of childhood deaths tend to occur during this first year, and after which there is a sharp drop in mortality risk, which ultimately levels out around the age of 10 to the low levels that characterize human adulthood. For most of human history and in many pre-epidemiological transition populations today, early childhood has been marked by elevated mortality risks, largely due to an increased susceptibility to infectious disease and, to a lesser degree, violence (i.e., infanticide). Under these circumstances, child mortality rates often exceed 200 per 1,000 births. However, in recent history, most populations have experienced a rapid reduction in child mortality risk, and developed countries often exhibit child mortality rates below 10.

Child Mortality in Traditional-Living Societies

Throughout the majority of human history, child mortality patterns were likely very different from those exhibited among modern developed populations and more similar to those observed among subsistence-level populations with little access to modern healthcare. Life tables for only a handful of such populations have been published. Among five modern hunter-gatherer populations, infant mortality rates average approximately 200 deaths per 1,000 births, ranging from 115 to 370. When looking at the first 5 years, child mortality rates average

approximately to 300, ranging from 190 to 450 (Blurton Jones et al. 2002; Early and Headland 1998; Gurven and Kaplan 2007; Hill et al. 2007; Hill and Hurtado 1996; Howell 1979). Infant mortality accounted for approximately two thirds of all child deaths, with annual mortality rates falling to around 50 per 1,000 in ages 1 through 4. Horticultural populations exhibit comparable child mortality rates and a similar pattern with infant mortality accounting for the majority of child deaths (Early and Peters 2000; Gurven and Kaplan 2007; Gurven et al. 2007; Neel and Weiss 1975; Wood 1980) (Fig. 1).

The similarity across subsistence-level populations suggests a human pattern that differs substantially from the extremely low mortality rates exhibited by populations with access to modern healthcare, as well as from the much higher rates exhibited by wild chimpanzee populations (Arias 2012; Hill et al. 2001). This pattern of reduced child mortality compared to other primates is likely a derived feature of the human life history pattern, which is realized through a variety of strategies. Human infants are born at about 6 % of average female body mass, larger than that of other great apes, and a larger percentage of this mass is composed of body fat (DeSilva 2011). However, mothers in natural fertility populations tend to wean their infants between 2 and 3 years of age, much earlier than the 4–6 years that is more typical of the other great ape species (Robson and Wood 2008). In other primates, weaning is associated with a cessation of caloric investment by the mother and an increased risk of nutritional stress in the offspring. In humans, however, nursing is replaced by provisioning. This decouples inter-birth intervals from length of investment, as mothers can continue to invest even after they give birth to subsequent children. Thus, human children can remain nutritionally dependent on caretakers for a much longer proportion of the lifespan compared to other primates.

In addition to enjoying a longer period of investment, children receive these investments from a number of different caretakers – mothers *and* fathers, grandparents, siblings, etc. In most

foraging populations, such caretakers rely on an even larger social network of producers who pool foraged resources, providing further nutritional stability to dependent children. Finally, caretakers can utilize their greater intelligence and cumulative cultural knowledge to manage the threats in the environments to a degree that is unachievable to virtually any other animal. All of these factors likely contribute to the reduction in mortality rates throughout childhood and, indeed, the entire lifespan.

Causes of Child Mortality

The causes of infant and child mortality vary across populations. Most demographic research among traditional-living populations relies on retrospective reports of past deaths, making the determination of exact causes of death challenging. Causes are therefore often grouped into broad categories, and a substantial portion typically remains unexplained. Congenital/birth afflictions and infectious disease tend to be the most common causes of infant mortality in these populations, with each accounting for comparable proportions of deaths (see references above for details). Neonatal deaths that occur shortly after birth due to congenital abnormalities and/or birth complications are often not specified beyond this general description. Regarding infectious diseases, respiratory diseases are reported as the most common cause of disease-related infant death in some populations, while in others, it is gastrointestinal disease (often accompanied by diarrhea). Infants are particularly susceptible to infectious diseases, as it takes time for the naïve adaptive immune system to mature and go through the process of clonal selection, so that it can become attuned to the local pathogen environment (McDade 2003). This process can be delayed by early pathogenic and nutritional insults, which were likely common in the low-energy balance, pathogen-rich socioecological conditions that characterized most of human history. During this early period of immunological naiveté, infants are buffered against infection by antibodies and other nonspecific immune defenses that are passed from mother to child via breastfeeding.

Child Mortality, Fig. 1 (a) Survivorship curves for hunter-gatherer populations. (b) Survivorship curves for horticulturalist populations. (c) Comparative survivorship curves.

Violence often represents another common cause of death of young children in traditional-living populations. Rates of infanticide, which can account for up to 40 % of infant deaths in some groups, vary substantially across populations and are largely affected by cultural trends. In many populations, infanticide is effectively nonexistent (see the section below on [Infanticide](#)).

During ages 1 through 4, infectious disease tends to account for a larger proportion of all deaths even though the rate of death by infectious disease itself declines. This is because the rates of death due to violence and congenital afflictions decline even more substantially. In some populations, however, violence remains a major cause of death (Hill and Hurtado 1996). Accidents

are often another major cause of death at this time, and rates of accidental death tend to be higher than those found among adults.

Kin Effects on Child Mortality

Human reproductive and parenting patterns are often characterized as a cooperative system, in which children receive investment from numerous caretakers (Hrdy 2005). These caretakers can reduce mortality risks in numerous ways. They can affect children's energy balances through provisioning and carrying, thereby reducing the risk of nutrition and immune deficiency-related deaths. They can provide protection from infanticide and environmental threats. They can watch over children to protect them from accidents. They can also provide aid to the mother so as to facilitate her ability to directly care for her children.

Many studies have explored the effectiveness of caretakers by calculating child mortality in the absence and presence of particular categories of caretakers (Sear and Mace 2008). Such studies are prone to issues of self-selection, as the absence of a common caretaker is often associated with other factors that also affect child mortality risk. Many of these challenges can be at least partly resolved through methodological and statistical means, however (Winking et al. 2011). All studies that have explored the impact of maternal presence on the mortality risks of infants and/or young children have reported significant effects, suggesting that maternal care is difficult to substitute. Similarly, a majority of studies exploring the impacts of grandmothers have found their presence to buffer children from mortality risks. Only a minority of those focusing on father presence have found such effects, however (Sear and Mace 2008).

Infanticide

In many populations, infanticide – the killing of an infant through active harm or willful neglect – is a common cause of child mortality, accounting for up to 40 % of infant deaths in some populations (Hill and Hurtado 1996). Cross-cultural reviews suggest that infanticide was historically practiced with some regularity in half to

two-thirds of the world's cultures (Daly and Wilson 1988). Infanticide is often perpetrated by the mother or other kin member because of a perceived inability to successfully raise the child to adulthood. Under extremely trying circumstances, neglect or infanticide might be considered the only viable strategy to ensure that limited resources are directed to those who can benefit from them (Scheper-Hughes 1993). In many of these populations, contraception and other means of family planning are unavailable, and infanticide is not viewed as an aberrant criminal act but a practice that is occasionally necessary for a family's survival. Methods of infanticide are varied but include deliberate killing (e.g., burying or smothering), placing the child in dangerous situations, and abandonment. Across cultures, the most commonly cited reasons for infanticide include circumstances that are unfavorable for rearing a child (e.g., short inter-birth interval, lack of male support), infant limitations (e.g., deformities, illness), and paternity issues (e.g., uncertain paternity, undesired paternity) (Daly and Wilson 1984).

In some populations infanticide is driven by gender preferences leading to vastly different rates of infanticide for male and female infants. This can be due to one sex being more likely to be deemed nonviable, as well as adults killing an infant because it is not the preferred sex. In most of these instances, female infants suffer higher rates of neglect and infanticide than male infants (Early and Peters 2000; Fuse and Crenshaw 2006; Hill et al. 2007; Hill and Hurtado 1996), although some populations do exhibit a preference for female infants (Cronk 1991).

Child Mortality in State-Level Populations

The demographic transition is the process by which populations move from a demographic profile characterized by high mortality and high fertility to one of low mortality and low fertility. The first stage tends to be defined by a rapid drop in mortality rates, which is often achieved via improved sanitation, nutrition, and access to healthcare. While this process began in the

1700s for some European countries, many began the process in the past century. Every region of the world has experienced declines in child mortality over the past 50 years with the global child mortality rate dropping by over 75 % (The World Bank 2015). The seemingly higher global rate compared to the regional levels is due to the fact that fertility rates tend to correlate with mortality rates, such that high-mortality populations are contributing disproportionate numbers of births to the sample. Sub-Saharan Africa remains the outlier region, even though child mortality rates have dropped by nearly 70 % in this region over the past half century. Currently, of the 20 countries with the highest child mortality rates, 19 are within Sub-Saharan Africa. Global infant mortality, which accounts for roughly two-thirds of child mortality, dropped by a comparable level over the same time period, changing from 114.8 in 1965 to 31.7 in 2015 (The World Bank 2015) (Fig. 2).

It is difficult to determine the relative impact of the many factors that have contributed to the overall reduction, but likely factors include access to vaccinations, better sanitation and access to clean drinking water, improved nutrition, anti-malaria efforts, and access to healthcare systems (Ahmad

et al. 2000). The United Nations made cutting child mortality rates by two-thirds the fourth objective of its 1990 Millennium Development Goals (United Nations 2016). While it failed to meet this goal by the 2015 deadline, mortality rates dropped by over half, and there is still a substantial effort to continue this trend. In 2014, the United Nations Children's Emergency Fund (UNICEF) spent nearly \$5 billion on numerous efforts related to children's well-being, many of which undoubtedly contribute to the continued decline of child mortality (United Nations Children's Fund 2015).

Causes of Child Mortality

Infectious disease continues to be the most common cause of child mortality, accounting for 64 % of global deaths occurring under the age of 5 in 2010 (Liu et al. 2012). Pneumonia and diarrheal diseases are the most common among these, and nearly all of such deaths are now preventable given access to appropriate medical care. Preterm birth and other birth/congenital complications account for another 29 % of child deaths. Among more developed nations and through time globally, child mortality is increasingly

Child Mortality, Fig. 2 Child mortality rates through time

dominated by neonatal death (that taking place between birth and 28 days of age), which now accounts for the majority of under-5 deaths in some regions (Liu et al. 2012).

Gender Biases

Typically, male children suffer a higher mortality risk than female children (Fuse and Crenshaw 2006; Sawyer 2012). Globally, the male infant mortality rate is approximately 15 % higher than the female infant mortality, and in Western countries, the difference often exceeds 20 %. This difference is generally attributed to a host of genetic and biological factors that cause naturally higher male mortality throughout the lifespan. Therefore, infant mortality rates closer to parity are taken to reflect gender-biased investment and/or harm that disadvantage female offspring. Infant mortality rate ratios (male/female) trend higher in highly developed countries and have increased globally in developing countries through time (Sawyer 2012).

Of particular note are China and India, the two most populous countries and two countries that have some of the lowest male/female infant and child mortality rates (Fuse and Crenshaw 2006; Sawyer 2012). These patterns have driven a large literature exploring the causes of this phenomenon and the potential demographic consequences of the so-called “missing girls.” The types and degree of gender bias vary throughout each large country and seem to be due to many complex socioecological and family-specific circumstances. Gender inequities appear to be diminishing in some regions, although overall trends suggest continued (and even increasing) gender differentials in major measures of wellbeing (Singh 2013).

Conclusion

For most of human history, the first 5 years of life, and the first year in particular, marked a particularly dangerous period for children, mostly due to a greater susceptibility to infectious disease. However, humans’ reproductive patterns differ in

many respects from those of other apes in ways that buffer children from the even higher mortality rates that nonhuman apes experience. These differences include a longer period of parental investment, direct provisioning, a greater number of caretakers, and cultural inventions designed to neutralize environmental threats. The continued decrease in child mortality in state-level populations, brought about through improved sanitation, nutrition, and healthcare, is simply an extension of this overall trend.

Child Support

T. Joel Wade¹, Kelsey Salerno¹ and James B. Moran^{1,2}

²Tulane University, New Orleans, LA, USA

Men and women have differing parental investments in their offspring and certainty of paternity plays a role in their parental investment (Trivers 1972). The sex with parental certainty is more likely to invest resources in their offspring than the sex with parental uncertainty. As a consequence of paternal uncertainty, men are more likely to leave their offspring and forego investment, shifting greater responsibility onto women to care for the offspring (Trivers 1972). Since it takes a considerable amount of resources to rear a child, women typically seek child support from men who do this. But, many men do not pay their child support. Consequently, child support enforcement policies were expanded and were more stringently enforced beginning in the twenty-first century in the hope of improving children's lives (Pirog and Ziol-Guest 2006; Wilson 2002). This shift is important because the mental and physical health of a child is impaired when the child does not live with both biological parents (Daly and Wilson 1985, 1986, 1988). But, many men are still reluctant to pay child support.

The US Census Bureau in 2011 stated that \$37.9 billion dollars in child support was owed during the year of 2011, and 53.4% of the individuals who were awarded child support were custodial single mothers (US Census Bureau 2013). Additionally, the percent of parents who reported receiving child support dropped from 52% in 2003 to 43.3% in 2011 (Grall 2013). This has continued with child support payment becoming less likely when a divorce occurs (Meyer et al. 2015). Evolutionary theory can provide an explanation or why this is occurring.

Researchers hypothesize eight evolutionary theory-based reasons why men refuse or reduce their child support payments (Shackelford et al.

2005, 2012). Men will refuse or reduce child support if (1) they are concerned that the custodial mother will use it to increase her attractiveness and fitness, decreasing the man's fitness. If a woman does this, the money may not reach the offspring and instead may be used to increase the mother's fitness, thus reducing the fitness of the male. A man will reduce child support (2) if the woman channels the resources to a new partner, if (3) he needs resources to obtain a new partner, and (4) if he needs resources to retain a new partner since women prefer men who can provide for them in the long-term (Buss 1989; Buss and Shackelford 2008). Therefore a male may reduce child support in order to show his new mate that he can provide for her. A man will also reduce child support (5) if he produces children with a new partner and this child lives with him (Manning and Smock 2000). Furthermore, reducing child support for noncustodial children could also be due to the child's age, since the cost of investing in an older child outweighs the benefits (Trivers 1974).

Furthermore, child support may be reduced (6) when confidence in paternity certainty is low or (7) when sexual access is terminated with the custodial mother. Finally, (8) men who engage in an affair or a short-term poach will refuse to pay child support when confidence in paternity of the offspring produced in the affair is low. This occurs because a man is at risk of investing in an offspring that is not his, and that decreases his fitness. Similarly, when a man does not resemble his offspring, he may be less likely to invest (Apicella and Marlowe 2004; Burch and Gallup Jr 2000; Gallup Jr et al. 2016) and consequently may be less likely to pay child support.

Child-Centered Learning

I-Fang Lee
School of Education, The University of
Newcastle, Callaghan, NSW, Australia

Synonyms

[Learner-centered education](#); [Student-centered learning](#)

Definition

A pedagogical practice that places the child's interests and learning needs at the center of education.

Introduction

The notion of child-centeredness can be traced in the writings of several “classic” Western developmental psychologists and educational philosophers of the eighteenth, nineteenth, and twentieth centuries including Jean Piaget, Lev Vygotsky, Urie Bronfenbrenner Jean-Jacques Rousseau, Johann Heinrich Pestolozzi, Friedrich Froebel, Maria Montessori, and John Dewey. Placing the child at the center, the concept of child-centered learning has multiple roots emerging from the fields of developmental psychology, philosophy, sociology, and education. In its contemporary pedagogical practices, child-centered learning has long been recognized as a progressive and innovative method for teaching students of all ages and learning abilities, ranging from early childhood, to primary, secondary, and tertiary education (Fallace 2015). To emphasize the

importance of placing the child/student at the center of education requires a radical shift in the teacher's self re-conceptualization and understanding of pedagogical practice about the child as a learner.

Narratives of Child-Centered Education: Multiple Constructions of Child-Centeredness

Child-centeredness has multiple origins and variations of theoretical orientation. Jean-Jacques Rousseau's novel, *Emile* (or *On Education*), coming from a European romantic construction of the child, outlined the nature of education and painted a particular cultural representation of the nature of the child as (s)he grows and develops into a (wo) man. Previously, before the eighteenth century, in Western civilization, the child was viewed as a miniature adult and was never the center of focus in sociocultural activities. However, in *Emile*, Rousseau depicted how a young boy should grow and develop under the adult's protection and guidance from early childhood, through adolescence, and into adulthood. In these early descriptions about the stages of learning and development, Rousseau's romantic narrative of *Emile* as a "noble savage" placed the child in the center of education, particularly in the early childhood years. Such a narrative about the child added new possibilities for a variety of sociocultural constructions of child-centeredness. Influenced by this romantic narrative of child-centeredness, several other prominent educational philosophers and theorists emerged to shape the (trans)formation of child-centered learning.

In the field of education, Johann Heinrich Pestolozzi's educational philosophy further amplified the romantic construction of the child and what his or her education should be to enhance development. As a student of Pestolozzi, Friedrich Froebel consolidated the idea of placing the child/person/student in the center of learning. Creating the concept of kindergarten, Froebel recognized and emphasized the importance of "seeing" all children as having unique learning needs and capabilities, placing the children at the center of education. His publications on educational

philosophy and method established the foundation of play and how teachers should understand the importance of children's play in order to facilitate children's learning and development. Froebel's creation of play materials (known as Froebel Gifts), designed to meet children's learning and development, was recognized as innovative and progressive. Froebel's work, as the father of kindergarten, established the notion of child-centered learning.

Maria Montessori's work in education follows a similar sociocultural construction of child-centered learning. With her medical background and through her early work with children of special needs in Rome, Montessori observed children's learning and development and drew on various physicians' and educators' work to classify children's development. Through the work of Jean Marc Gaspard Itard and Édouard Séguin, Maria Montessori developed her "scientific" approach to education and established a framework of child/human development to identify the child's developmental stages. Placing the child in the center of education, Maria Montessori's classroom design was meant to be a well-prepared and sequenced learning environment for the child. Conceptualizing the child as an active learner, a Montessorian perspective of a child-centered environment recognizes that the child is not passively waiting to be taught by the teacher or for knowledge to be transmitted from the teacher to the child.

Meanwhile, in the field of cognitive psychology, Jean Piaget's and Lev Vygotsky's cognitive developmental frameworks further pushed the (trans)formation of child-centered pedagogy in the field of education. Piaget's stages of cognitive development theory greatly influenced teachers' understanding of how children develop and learn in classroom settings. Similarly, Vygotsky's sociocultural cognitive development theory has broadened contemporary educational practices, shifting pedagogical practice in classrooms to facilitate children's learning and development. While their theoretical frameworks of cognitive development and constructivist approaches to the child's learning and development are very different, both Piaget's and Vygotsky's works significantly influenced the spread of child-centered

learning pedagogical practices in the field of education.

These multiple narratives of child-centeredness from different fields of study have all worked to legitimize the notion of child-centered learning as innovative and progressive pedagogical practice. Placing the child in the center of education has never been questioned of as a truthful, universal, appropriate, contemporary educational practice. Therefore, it is important to destabilize the popular conception of child-centered learning, for it has been a dominant Western narrative of learning and development for centuries. The need to unpack and problematize the cultural conflicts of child-centered pedagogy cannot be ignored.

Critical Reflections on Child-Centered Learning

The dominant constructions of child-centeredness across contemporary global education systems have primarily reflected Western sociocultural narratives of the child to form the basis of child-centered pedagogy (e.g., see Lee and Tseng 2008). While it is significant to place the child in the center of his/her education to support and facilitate the child's learning and development, it is also important to raise critical questions to unpack hidden sociocultural bias in the dominant narratives of child-centeredness. Critical questions such as "*whose child has been placed at the center of education*" should not be ignored, since most of the well-known pedagogical approaches in education that promote child-centered learning all have cultural roots of Euro-centric or Anglo-Saxon political and sociocultural assumptions (Dahlberg and Moss 2005). For example, Froebel's idea of child's play, Montessori's conception of child-centered pedagogy, Piaget's cognitive development theory, and Vygotsky's sociocultural cognitive developmental perspectives are related to Western sociocultural backgrounds (Burman 1994; Cannella 1997). These variations on similar constructions of child-centeredness are sociocultural inventions in that "the child" is a particular type of child through which the conceptual formation of child-centeredness and child-centered learning

can privilege certain group(s) of children only. Therefore, it is imperative to unpack the bases of the *kinds* of knowledge that come together to shape the specific sociocultural constructions of child-centered learning for all children.

While acknowledging the importance of child-centered learning to support children's development and learning, contemporary critical theories have not been taking the notion of "child-centered learning" at face value. For instance, to challenge the notion of "child-centeredness" as a progressive education and pedagogical practice, it is important to reconceptualize that knowledge is never neutral, but is constituted within complex webs of power relations with social, cultural, political, and historical influences (Apple 2000). The question of "whose knowledge counts" as the "universal" truth when it comes to shaping "our" understanding of child-centered learning has opened up possibilities to destabilize the grand narrative of child-centeredness. Additionally, if the notion of child-centered pedagogy is not problematized or reconceptualized, it is ironic that many children will be excluded from the center of education and their different learning needs and development may be silenced.

Conclusion

In the twenty-first century, child-centered learning is a much promoted educational philosophy and pedagogical practice. The main rationality of child-centered learning pedagogy is to place the child in the center of teaching and learning for the cultivation and facilitation of an active learner as well as to foster the child's/learner's autonomy and independence in his/her own learning process. Additionally, with strong roots in the field of cognitive psychology, child-centered learning acknowledges the child as an active learner who has a voice and agency in his/her learning process and development. In contrast to the traditional education approach that is teacher-centered, the notion of child-centered learning does not see the teacher as the primary source of knowledge. Rather, knowledge is co-constructed between the child and the teacher in child-centered learning pedagogical practice.

Children and Sibs Share Same Proportion of Genes

Synonyms

[Genetic relatedness](#); [Kin relations](#)

Definition

Individuals share approximately the same amount of genes with their biological children and with their full siblings.

Introduction

Biological parents share an average of 50% of the same genes with their children and step-parents share 0% of the same genes with their stepchildren. Adoptive parents can either share some genes with their adoptive children (in the case of within-family adoption) or not. In addition, individuals share approximately 50% of their genes with their full siblings, 25% of their genes with their half siblings, and 0% of their genes with their step-siblings. In the case of within-family adoption, siblings can be genetically related, but in the case of outside family adoption, they tend to be unrelated.

Although individuals share approximately the same proportion of genes with both their biological children and their full siblings, these relationships are substantially different from each other. Sibling relationships are typically horizontal because siblings are often close in age and therefore belong to the same generation. Relationships between parents and children, however, are vertical by nature because parents are always older than their biological children, meaning that parents and children do not belong to the same generation. Relationships between two siblings are usually equal and reciprocal, but parents invest much more time and resources in their children than they can ever assume to receive back (Del Giudice and Belsky 2011).

Across human societies, mothers have been the most important individuals to guarantee children's survival and well-being (Sear and Mace 2008). Older siblings can act as "allo-parents" and increase the survival of their younger siblings, but individuals' investments in siblings are far lower than parental investments in children. Moreover, compared to

parent-child relationships, sibling relationships include more competition by nature because siblings can compete with one another for parental resources (Salmon and Hehman 2014).

Relatedness and Kin Investment

Based on inclusive fitness theory, the degree of genetic relatedness explains how altruistically individuals act towards one another. Several studies have provided support for this prediction (see Volk 2011 for review). An increasing amount of studies indicate that fathers who have biological children invest more in their offspring compared to fathers who have children via their spouse. Stepfathers are also more likely to neglect their stepchildren than biological fathers are to neglect their biological children. However, in the case of adoptive children, parental investment can be as substantial as with biological children (Segal et al. 2015).

In the case of siblings, the degree of genetic relatedness influences sibling relationships (see Pollet and Hoben 2011 for review). Studies have reported that siblings who share both biological parents are closer to one another compared to step-siblings. Moreover, full-siblings tend to have closer relationships and more contact than half-siblings. Finally, some recent studies have detected that individuals may also have more conflict with their full rather than their half-siblings, at least when less severe conflicts are measured (Salmon and Hehman 2015; Tanskanen et al. 2016), indicating that small disagreements may forecast good rather than bad kin relationships.

Conclusion

Although the degree of genetic relatedness is similar between parents and biological children and between siblings who share both biological parents, parent-child, and sibling relationships differ from one another. In general, the net flow of resources tends to go from parents to their children. Although siblings are often emotionally

close to one another, parents and children form a special bond across societies. Perhaps the most important similar aspect between sibling and parent-child relationships is that in both of these kin relationships, the degree of genetic relatedness may make a difference. Individuals tend to invest more resources in their more closely related kin than in less or nonrelated kin.

[Age-related reproductive potential](#); [Future reproductive capacity](#); [Reproductive potential](#)

Definition

On average, individuals share 50% of the same alleles with their children and with their full siblings. Because of age-related reproductive potential, however, it is often more evolutionary beneficial to invest time and resources in children than in siblings.

Introduction

Evolutionary theory predicts that kin investments are dependent on the potential fitness benefits of the investments that are related to recipients' current and future reproductive potential (Hughes 1988). For instance, although a 55-year-old mother shares 50% of the same alleles with both her 18-year-old daughter and 65-year-old sister, in terms of her inclusive fitness, it is more beneficial to invest resources in her daughter than her sister. This is because her 18-year-old daughter has a potentially high reproductive capacity, but her 65-year-old sister is already beyond her reproductive years. Investing resources in children at the beginning of their reproductive careers may maximize the investors' number of offspring in future generations.

In addition to age, reproductive value is also sex-specific. Although the fertility of both females and males declines with age after they have reached their sexual maturity, males can still reproduce until they die, but human females experience a long nonreproductive lifespan. The reproductive value of children is highest at the beginning of their reproductive years when their potential time to have their own children is long and they are most fertile (Trivers 1971).

Reproductive Value and Kin Investment

The reproductive value prediction has been tested in some previous empirical studies with respect to children and siblings. For instance, children with disabilities need more parental investment and are less likely to provide fitness benefits because they have a lower probability to reproduce if they even survive (Salmon and Malcolm 2011). Therefore, infants who are born with disabilities are more likely to become victims of parental infanticide compared to children without such disabilities (Daly and Wilson 1984). From a fitness perspective, it would be more beneficial to parents to abandon investment in children with disabilities and to invest in other offspring with higher reproductive potentials.

A set of studies has tested the reproductive value hypothesis in sibling relationships. These studies have found that childless couples more often take care of their siblings' children compared to couples with children (Pollet and Dunbar 2008) and that childless women have more contact with their siblings with children than their siblings without children (Pollet et al. 2006; Tanskanen 2015). These results indicate that individuals who do not have children of their own may try to increase their inclusive fitness by investing in their kin in descending order, providing evidence for the prediction that the recipient's reproductive value shapes human behavior (Pollet and Hoben 2011). Moreover, studies on non-human species have shown that reproductive value is associated with the time and the resources that individuals direct towards their kin (Emlen 1984).

Conclusions

Based on inclusive fitness theory, for childless individuals, investing resources in their siblings with children could be the most beneficial strategy to increase their own inclusive fitness, particularly when it is unlikely that these individuals will have their own children because of older age or some other reason. Reproductive value may also explain why individuals tend to invest more resources in their children than their siblings, although the degree of relatedness between them is similar. By investing time and resources in their offspring in descending order, individuals can maximize their number of descendants in future generations.

higher socioeconomic status in adulthood (Geary 2005). Though this research has established the generalized importance of paternal investment for both sons and daughters, some of the most reliable and pronounced associations revealed in this literature are those between low paternal investment and daughters' developmental, sexual, and reproductive outcomes.

Children Without Paternal Investment

Danielle J. DelPriore

University of Utah, Salt Lake City, UT, USA

Pennsylvania State University, Altoona, PA, USA

Synonyms

Father absence; Low-quality fathering; Paternal disengagement

Definition

Offspring who receive no (or low-quality) parental care, financial or emotional support, or other fitness-relevant resources (e.g., energetic, social) from their biological fathers.

Introduction

Social scientists have long recognized the importance of families, in general, and parents, in particular, in shaping children's outcomes (for better or for worse). Although past work has largely focused on the effects of joint parenting processes or maternal behavior on children's well-being, more recent investigations have examined the unique impact of a father's investment on sons' and daughters' outcomes. In general, this research suggests that for children across cultures, growing up with (versus without) the investment of one's father is associated with a wide range of social and physical benefits, including reduced mortality risk and illness, greater academic achievement, and

The Effects of Low Paternal (Versus Maternal) Investment

Research on the influence of physical father absence (including parental divorce) on daughters indicates that growing up without (versus with) one's biological father in the home is associated with accelerated pubertal development (James et al. 2012), early initiation of sexual activity (Ellis et al. 2003; James et al. 2012), increased risk of teenage pregnancy (Ellis et al. 2003), and increased risky sexual behavior, such as having sex with a greater number of partners and having unprotected sex (Coley et al. 2009; James et al. 2012). Although disparities between daughters from intact and divorced homes are apparent across development, some research suggests that these group differences are most pronounced when physical separation from the father occurs early in life (Ellis et al. 2003).

Low paternal investment that results from physical absence of the father is reliably associated with accelerated and unrestricted sexuality among daughters; however, low-quality father–daughter relationships may take on similar (if not greater) importance in shaping these outcomes. Low-quality fathering – whether indexed by low levels of warmth, emotional closeness, or involvement in children's lives – is associated with accelerated sexual development, early sexual onset, and increased sexual risk taking among daughters, even when the biological father remains in the home (e.g., Coley et al. 2009; Ellis et al. 2012; Rink et al. 2007). Importantly, such relationships persist when controlling for unmeasured genetic and environmental confounds (e.g., genetic risk for problem behavior, poverty) by comparing the behavior of biological sister pairs with differential exposure to their

fathers, suggesting a causal relationship between paternal behavior and daughters' sexual risk taking (Ellis et al. 2012). Accordingly, low-quality father–daughter relationships can be a more important risk factor for risky sexual behavior than physical father absence from the home.

Though a mother's investment undoubtedly influences adolescent outcomes, it may be fathers who exert a stronger, unique impact on daughters' sexuality. For instance, Rink et al. (2007) demonstrated that increased father – but not mother – connectedness decreased daughters' likelihood of engaging in early sexual behavior. Ellis et al. (2012) found that increased exposure to low-quality fathering (indexed by low warmth and high harshness) predicted increased risky sexual behavior among daughters from biologically disrupted families, even after controlling for the quality of the relationships that daughters had with their mothers. The reliable impact of fathers (versus mothers) on daughters' sexuality may derive from the information that paternal investment patterns provide daughters about the availability of male investment in their local environments (i.e., paternal investment theory: Draper and Harpending 1982; Ellis et al. 2012). On this view, receiving low (or no) investment from the father lowers daughters' expectations for receiving long-term investment from male relationship partners, instead shifting them toward relatively short-term (“fast”) reproductive strategies.

Low Paternal Investment and Adolescent Risk Taking

From the perspective of paternal investment theory, the effects of a father's investment on sexual behavior will be more pronounced for daughters relative to sons. However, this does not suggest that paternal investment has no impact on sons. Veneziano (2003) explored the effects of paternal warmth and physical presence on boys' interpersonal aggression (including theft and homicide) among a culturally diverse sample. The results of this research suggested a link between increased paternal warmth and decreased interpersonal aggression among boys. Other work has found

parental divorce/separation (including single parenthood) to be an equally strong predictor of early sexual behavior among adolescent boys and girls (e.g., Flewelling and Bauman 1990).

Despite evidence that fathers' behavior (or absence) can impact boys' aggressive and sexual tendencies, when directly comparing the effects of paternal investment on sons' and daughters' sexual outcomes, many studies suggest stronger fathering effects for daughters than for sons. For instance, Coley et al. (2009) revealed that increased paternal knowledge reduced sexual risk taking among daughters more than it did for sons. Similarly, James et al. (2012) found that father absence from the home directly increased the likelihoods of early sexual debut and risky sexual behavior among daughters but not among sons.

The logic of paternal investment theory also suggests that the effects of fathers on daughters should be most pronounced for risky *sexual* behavior and should not necessarily extend to influence other forms of risk taking. Despite some research suggesting that paternal disengagement can have implications for adolescents' willingness to take sexual *and* nonsexual risks (e.g., substance use; Flewelling and Bauman 1990), other studies have failed to reveal a strong or reliable effect of paternal disengagement on daughters' nonsexual risk taking. To illustrate, Mandara and Murray (2006) examined the effects of father absence on adolescent drug use and found that father-absent boys were more likely to use drugs than father-present boys. However, father absence (versus presence) did not significantly increase girls' reported drug use.

Further, whereas early father absence is a strong predictor of girls' increased risk of early sexual activity and teen pregnancy, Ellis et al. (2003) found that exposure... to father absence does not uniquely predict the occurrence of nonsexual problem behaviors (e.g., violent acts, externalizing behavior problems) after controlling for other risk factors (e.g., family life stress). In light of the mixed support for father absence being associated with different forms of nonsexual risk taking, it appears that the unique effects of fathers may be most pronounced and consistent for

daughters' engagement in early and unrestricted sexual behaviors.

Conclusion

Does a father's investment matter, and if so, how? The empirical evolutionary developmental literature has taken important steps in addressing these questions. In traditional societies, the investment of a father can mean the difference between life and death for a developing child. In modern, Western societies characterized by low child and infant mortality, a father's investment may provide other critical advantages, such as better health and the promise of future socioeconomic success (Geary 2005). Although these advantages are enjoyed by children regardless of their gender, paternal investment may be most influential in shaping daughters' mating outcomes. On this view, a father's investment provides information to daughters suggesting that men are able and willing to invest in reproduction, and as such, reproduction can be delayed until such investment is secured. Daughters may thus attend to cues such as the father's presence in the home and his behavior (e.g., his level of warmth and support directed toward them and their mother) in calibrating emergent reproductive strategies. From a functional perspective, this approach makes good adaptive sense, allowing females to avoid (or capitalize on) potential reproductive opportunities based on what they can reasonably expect from males within the local ecology.

Threat avoidance

Definition

Numerous physiological, cognitive, and cultural cues help children avoid a range of threats and predators.

Introduction

Predator avoidance is greatly prioritized across humans and the animal kingdom. Furthermore, organisms that lack the ability to adapt to environmental demands will face casualties in the “war of nature” (Darwin 1871; Mobbs et al. 2015). Thus, researchers across several disciplines have studied the various adaptations protecting individuals – including infants and young children – from predators. Of these, physiological, cognitive, and cultural mechanisms are discussed.

Neuroanatomical and Physiological Mechanisms

Öhman's (1993) evolved fear module describes a neural system tuned to evolutionarily relevant threats. The module is selective, automatic, and independent of conscious cognition. Located in neural circuitry centered in the amygdala (within the anterior temporal lobe), the module mediates threats (e.g., detecting a snake or spider) and appropriate responses (i.e., fight or flight) before fearful stimuli are fully identified across regions of the cortex (Öhman and Wiens 2004).

One paradigm often used to support this neural system for fear involves measuring event-related potentials (ERPs) utilizing an electroencephalogram. ERPs reflect cortical activity, which can inform neural processing and responses to a variety of stimuli, for example, how soon a stimulus is detected after it is presented to a participant. Researchers have measured children and adolescents' early detection of fear in the amygdala (Monk et al. 2008). The amygdala operates as a quick detection fear module within the brain, which in turn enables the experience and perception of fear (Fox et al. 2007). Researchers have measured amygdalar activation from a range of

emotional stimuli across adults, adolescents, and children (Guyer et al. 2008; Hare et al. 2008; Passarotti et al. 2009). Additionally, both Gee et al. (2013) and Pfeifer et al. (2011) have demonstrated the amygdala's connection to emotion reactivity. Additional work with children, some utilizing ERPs, others utilizing functional magnetic resonance imaging (fMRI), supports the role of the amygdala (Forbes et al. 2011), hippocampus (Pagliaccio et al. 2015), and prefrontal cortex (Monk et al. 2008) in threat detection.

Arousal data also hint toward an evolved fear module, with various measures showing immediate physiological responses to threat. Fear is represented in a variety of physiological responses (i.e., rapid heart rate, skin conductance, pupil dilation). In one study, Weems et al. (2005) explored skin conductance and heart rate in 6–17-year-olds following exposure to a mildly phobic stimulus (e.g., a video of a large dog). Their findings suggest both physiological responses are linked to anxiety (a component of fear); however, the association for heart rate was higher. Weems et al. (2005) explained that, while both are reasonable measures to consider in these studies, heart rate is the better measure because the amygdala (where threat is detected) has a stronger influence on heart rate (Thayer et al. 2012). Field and Schorah's (2007) research further supports that notion. In their study, children between 6 and 9 years old were asked to place their hand into a box that contained fearful, positive, or neutral information about animals. Their findings revealed there were significant differences between heart rate among the boxes, including a significantly higher heart rate when children approached the box with threat-related information, relative to the box with neutral information.

Skin conductance responses (e.g., sweating) reflect changes within the sweat glands that then produce changes in the electrical conductivity of our skin. Because this reflects activity across the sympathetic nervous system, it further provides a useful metric for arousal (Jovanovic et al. 2014). In their research, Gao et al. (2010) investigated skin conductance responses in fear conditioning among children 3–8 years old. Results suggested fear conditioning increases in children at a very

early age, beginning between the ages of 5 and 6. Glenn et al. (2012) further showed that with conditioned stimuli, responses were elevated for 10–13-year-olds, again showing skin conductance can provide important insights for conditioned fear.

Adaptations to threat exist in children in the early stages of development, suggesting some responses to fear are not learned. Examples of these include immediate processing in their amygdalae, followed by strong sympathetic responses most evident in children's heart rate.

While children's physiological responses to threat detection can differ, researchers argue heart rate and skin conductance responses are the most common and reliable measures. Of equal importance, children ought to use these physiological signals to guide their behavior and responses to threat (Howle and Kazanas 2019).

Cognitive Mechanisms

Adults' attentional biases for threat-relevant stimuli are well-established in the cognitive literature (e.g., Öhman et al. 2001). Öhman's (1993) evolved fear module predicts adults and children should behave similarly, with both age groups needing to rapidly detect and avoid threats in their environment. To test this hypothesis with young children, LoBue and DeLoache (2008) modified the typical visual search paradigm with the addition of a touchscreen monitor. They asked 3–5-year-old children and their parents to detect targets from distractors, when targets were either snakes, flowers, frogs, or caterpillars. Participants identified targets by touching the single target embedded among the distractor stimuli. Across three experiments, adults and children performed similarly: each time, detecting snakes faster than each of the nonthreatening distractors (see Penkunas and Coss 2013b for a replication with snakes and lizards). They replicated these findings with 8–14-month-old infants, as well, when snakes were displayed among flowers and frogs (LoBue and DeLoache 2010). Importantly, infants detected snakes only *numerically* faster than frogs (i.e., this difference was not significant), hinting

toward the possibility of some generic animacy effect at this young age (c.f. Altarriba and Kazanas 2019), rather than an explicit mechanism for detecting snakes.

Nevertheless, the attentional bias for detecting snakes observed by LoBue and DeLoache (2008) has been tested with other groups of children. In one example, Penkunas and Coss (2013a) determined these patterns for threat detection replicate with non-Western populations, including 3–8-year-old children living in Southern India. In one particularly notable finding, the rural and urban children performed similarly: both with shorter latencies to locate the target when it was a snake or a lion than when it was a lizard or an antelope. Importantly, the rural children live in or near national parks (some even in tiger reserves), while the urban children do not regularly encounter these threats. Thus, it appears neither experience nor novelty played a role in these comparisons.

In one recent paper, experience *did* play a role in threat detection. Prokop (2018) asked parents to describe their child's recent medical history, identifying children as "vulnerable" if they had contracted some infectious disease in the past year. Then, 5–6-year-olds and 8–9-year-olds were asked to identify predators (e.g., wolves), disease carriers (e.g., mosquitoes), and animals aposematically colored (i.e., those warning off predators with their appearance, e.g., skunks) from control animals (e.g., zebras). Predators were identified most accurately, as we would expect from this literature, but, critically, children identified as vulnerable were especially successful at identifying disease-carrying animals. This particular finding suggests animacy, particularly predatory threats, helped shape important elements of human cognition (e.g., adaptive memory; Kazanas and Altarriba 2015, 2017; Kazanas et al. 2020). Perhaps, then, the more vulnerable react faster, thanks in part, to some connection to their behavioral immune system.

Other researchers have wondered *how* these biases occur, perceptually. LoBue and DeLoache (2008) reviewed earlier hypotheses from the visual search paradigm, such as Treisman and Gormican's (1988) important features, most

notably, curved lines. For example, perhaps a snake's tendency to slither or coil their elongated, limbless body somehow mattered in human evolution. Years later, they confirmed this idea, with children and adults detecting coiled wires faster than flowers, and no advantage for snakes when they were *not* presented in a coiled shape (LoBue and DeLoache 2011; see also DeLoache and LoBue 2009 for a similar argument with an emphasis on movement). We cannot be sure precisely why a curved shape garners this advantage, unless snakes shaped the far earlier primate visual system, too (Isbell 2006). Rakison and Derringer (2008) made a similar case for our tendency to rapidly detect spiders: Infants as young as 5 months old looked longer at schematic spider imagers than they looked at reconfigured versions of these images (while they do not appear to have any templates for flowers at this age). Thus, at such a young age, we can observe attentional and perceptual mechanisms shaped by threatening stimuli.

Hansen and Hansen's (1988) "face in the crowd hypothesis" predicts children will also demonstrate attentional biases for faces, particularly angry faces appearing among nonthreatening faces. LoBue (2009) sampled both adults and preschoolers, to see if experience conflates this hypothesis. She compared a variety of positive and negative facial expressions, testing whether (1) we are particularly sensitive to angry faces or (2) we possess something akin to a general negativity bias (Cacioppo et al. 1999; Smith et al. 2003). Her participants completed a number of visual search tasks, with targets and distractors comprised of angry, afraid, sad, and happy faces. Findings from the first three experiments supported a general negativity bias, with faster latencies to touch the target when it was an angry, afraid, or sad face, relative to a happy face, suggesting these negative expressions were easy to detect. Importantly, the next set of experiments compared latencies when both targets and distractors were negative expressions. Critically, participants detected angry and afraid faces the fastest, evidence of an attentional mechanism built to rapidly attend to danger in the environment.

Perhaps the strongest evidence of this mechanism lies in the similar patterns of data across adults and preschoolers. While adults *did* perform the tasks faster, both age groups displayed the same attentional biases to negative expressions and their latencies to touch the target were the fastest for angry and afraid targets. This broadly implies an evolved bias to rapidly detect threats – otherwise, young children without the experience (explicit or otherwise) would not have known to react this way to a threat, barring any novelty effects, of course. Additional research, perhaps with infants, could disentangle some of these additional explanations. For example, LoBue and DeLoache (2010) examined attention biases with 8–14-month-old infants, finding rapid orientation to angry faces (Experiment 2), but not to afraid faces (Experiment 2A), though they looked at them longer than they looked at happy faces. We can only surmise infants are using these moments to learn about potential threats in their environment. One final point worth mentioning: LoBue and DeLoache (2009) have also detected some (small) tendency for young girls to detect targets faster than young boys, but *only* when the targets feature emotional expressions. Moreover, this advantage occurs whether or not these expressions are categorized as threat-relevant (i.e., angry, afraid) or not (i.e., happy, sad). Replications can bolster the reliability of these trends in the literature.

In one final paradigm, Hoehl and Pauen (2017) examined fear acquisition in 9-month-olds with gaze-cueing. In this paradigm, researchers use ERPs – at key locations – to infer attentional biases, such as increased attention when a fearful face is shown looking at a spider. In this case, the authors measured attention by way of the negative central component: a measure of infant attention particularly sensitive to emotion (Hoehl et al. 2008). Fearful and neutral faces were presented next to threatening or nonthreatening stimuli (e.g., spiders and snakes vs. flowers and fish). For example, in Experiment 2, Hoehl and Pauen observed increased attention to snakes, regardless of the face paired with it. This further hints to an evolved fear for snakes (c.f. Poulton and Menzies 2002). Meanwhile, in Experiment 1, featuring

spiders and flowers, the authors observed only some increased attention when fearful faces were paired with spiders, though this interaction was not significant. This finding suggests infants may take cues from others' emotional expressions when learning about their environment, showing a particular sensitivity to their *fears*. Universal attentional biases – such as the ones observed with snakes – suggest some fears are more easily developed, whereas others perhaps develop after an experience or from some amount of social learning.

Cultural Mechanisms and Individual Differences

Cultural upbringing greatly shapes a child's interaction with a stranger. Cultural contexts including “the economy, social structure, settlement pattern, and household and family organization” shape a child's learning environment and influence their behavior (Whiting and Whiting 1975, p. 66). For example, Otto et al. (2014) studied Nso children in the South African country of Cameroon and in Germany to determine if the cultural contexts in which a child grows and learns in shape their interactions with strangers. To test this hypothesis, a stranger was introduced to a mother and year-old child in their family home. The stranger was instructed to hold and play with the child for 3 min with play including holding the child and interacting with toys and games. Overall, Otto et al. found significant differences in child interaction with the stranger. German children were less likely to comply with stranger wishes while Nso children were more likely to conform to the wishes and suggestions of the stranger. This significant difference in interactions with strangers is supported by the beliefs of each of the culture in the study. German caregiving is child-centered and German parents focus on child socialization to include assertiveness, individualization, and self-actualization (Keller et al. 2006, 2009; Keller and Otto 2011), while Nso mothers focus on teaching their children obedience, conformity, and a respect for authority (Otto and Keller 2015).

Another effect of culture on child interaction with strangers may stem from own-race bias and homogeneity of the area in which the child grows up. Bar-Haim et al. (2006) studied 3-month-old Caucasian Israeli children, African Ethiopian children, and Israeli-born infants of Ethiopian origin to assess preference for own-race faces versus other-race faces. In this study, children observed African and Caucasian face-pairs and researchers noted their direction of gaze and its duration. The results of the study showed Caucasian children looked longer at Caucasian faces than African and the opposite was found for African children. Interestingly, the Israeli-born infants of Ethiopian origin showed no face preference for either Caucasians or Africans. The children that showed a race-preference came from homogeneous race environments. This race-face bias may indicate children raised in homogeneous race environments may be averse to those who are from outside of their usual environment.

A similar study by Gaither et al. (2012) found Caucasian, Asian, and biracial Caucasian-Asian children in Los Angeles showed no race preference for faces. This result makes sense as Los Angeles is a very racially diverse area, meaning that these children are more likely to be exposed to other races at a higher rate than children in more racially homogeneous areas. The study found that when asked “What percentage of time do you spend with people not of your same race and/or culture?,” parents noted a high percentage of exposure to others outside of their own race. The results of these two studies broadly imply children from homogeneous locations are going to be more likely comfortable around those who look like them and their own family, with an aversion to those who do not share those same appearances. These children may become fearful of those from other races or cultures, unless they are socialized with those different than them later in life.

Other researchers have looked at the influence of parents on child responses to strangers. Trause (1977) studied 40 infant-mother pairs that were approached by a stranger, followed by the mother leaving the child and allowing a stranger and child interaction that included talking to the child, touching the child, and attempting to hold the

child for 30 s. Half of the mothers stayed with their child for 3 min and the other half stayed with the child 10 min before leaving. All the infants were alone with the stranger for 13 min. Once the mother left, stranger approach toward the child elicited significantly more negative reactions than it did when the mother was present. The presence of the mother moderated the child's response to the stranger.

Lamb et al. (1982) took a different approach than the previous authors and studied children's attachment to both their mother and father to determine the effects on stranger interactions. When the parents and children first arrived, child sociability was measured by their behavior in different scenarios, once with the father and once with the mother. Half of the children interacted with a male stranger and the other half a female, for both measures. After the child's sociability was measured, the Strange Situation (Ainsworth et al. 1978) occurred, which measured attachment to the individual parent. Children with secure attachment with high contact relationships with their fathers were significantly more sociable than those with avoidant attachments and secure attachments with low contact. Infants who were securely attached to their fathers were marginally more sociable than those children who were insecurely attached. Interestingly, there was no significant relationship between mother and child attachments and sociability with strangers. This finding is surprising, because previous studies found infants who are securely attached to their mothers are more sociable to strangers than those who are insecurely attached (Main 1974). Regardless of the differences in results according to the parent gender, children with an insecure or avoidant attachment are less sociable to strangers than those who are securely attached.

A final study of parental influence on children's response to strangers studied children in single- and two-parent families. Weinraub and Ansul (1985) aimed to determine if children from single- and two-parent households respond differently to male and female strangers, if maternal stress influences mother-child interactions and thusly affect child response to strangers, and if the quality of mother-child interactions affect child

response to strangers. Thirty-eight mother-infant pairs (19 single-parent family, 19 two-parent families) participated in this study. Child responses to male and female strangers, in the presence and absence of their mothers, were studied using a modified form of Ainsworth's Strange Situation (Ainsworth et al. 1978). Children from single-parent families showed more fearful behaviors toward both strangers than those from two-parent families. These children ignored requests to play or to be comforted by the stranger significantly more often than two-parent children. Single-parent children tended to cry more when left alone with the strangers and tended to express more negative verbalizations toward the strangers than their peers.

Each of these studies shows parents have a great effect on their children's response to strangers. Children who are not securely attached, in the presence of a parental/maternal figure, or those from single family homes are more likely to have negative responses to a stranger. These responses are often fearful and less sociable toward the stranger, with behaviors to ward off the stranger including crying, negative verbalizations, physically distancing themselves, gaze aversion, and refusal to play (Lamb et al. 1982; Trause 1977; Weinraub and Ansul 1985).

Finally, gender plays a large role in infant response to strangers. Gender differences in response to strangers have been identified in several studies. Boys are often more stable and positive in their interactions with strangers than girls, while girls engage in fewer social interactions with strangers, avoid the stranger more, and are more likely to show negative responses to the stranger as time or attempt at contact with the stranger increase (Shaffran and Decarie 1973; Trause 1977; Weinraub and Ansul 1985).

Gender of the stranger is even more significant in affecting the response from children. Overall, children respond more negatively to male strangers than to female strangers (Lamb et al. 1982; Shaffran and Decarie 1973). This male aversion was also shown in Weinraub and Ansul's (1985) study. Children made significantly more approaches and tended to remain in close proximity more frequently to their mother in the presence

of a male stranger than a female stranger. Significantly more exploratory behaviors were displayed in front of the female than the male stranger, with children engaged in more exploratory manipulation, such as playing with toys in the room. One explanation for this male aversion by children could be the height of the male versus the female stranger (Brooks and Lewis 1976; Lewis and Brooks-Gunn 1972).

Conclusion

Findings from several lines of inquiry support the role of threat in shaping children's responses toward predators. Those responses are evident in children's arousal, but also in their outward attention toward and fear of dangerous animals, angry faces, and adult strangers. Throughout our evolution, automatic, and almost universal, attention toward these predators, along with appropriate responses (e.g., avoid, rather than approach), has ensured our children's safety. However, these responses are also strengthened by a culture's or individual family's attitudes toward strangers. Together, these findings emphasize the importance of both innate and learned mechanisms in understanding an individual child's response. Further, the most fine-grained understanding comes from also considering a child's age, gender, and other dispositional characteristics, along with understanding that some findings may not generalize to all children, from all cultural contexts. Future research with these considerations in mind, paired with multimethod approaches, can further our understanding of children's inward and outward antipredator behaviors.

Synonyms

Between-community raiding; Border patrols; Coalitionary killing; Conspecific killing; Gang attacks; Intergroup aggression; Intergroup conflict; Lethal raiding; Lethal violence

Definition

Lethal raiding is a form of coalitionary, intergroup aggression observed in chimpanzees in which a party leaves its core range to find and attempt to kill strongly outnumbered and isolated members of neighboring communities.

Introduction

While intergroup conflict is common in social animals, fatal aggression is rare and usually a result of accidental injury during escalated fights (Manson and Wrangham 1991). However, in some species, such as chimpanzees and humans, intergroup aggression appears to be marked by coalitionary, apparently deliberate attempts to kill conspecifics. In chimpanzees, this behavior is likely facilitated by their fission-fusion dynamics, male philopatry, and resource defense polygynandry. We review several proposed hypotheses on the adaptive function of this behavior, which are not mutually exclusive. Critics of this adaptive interpretation suggest that lethal raiding is caused or exacerbated by human disturbances to chimpanzees, though this is not strongly supported by the current evidence. Chimpanzee raiding shares several characteristics with human warfare and is therefore often part of the debate on the origins of human warfare.

Intergroup Conflict in Chimpanzees

Across social species, contest competition for access to limited resources can result in conflict between groups (e.g., Kitchen and Beehner 2007; Radford 2008). Such intergroup conflict may range from avoidance by one group or exchange of aggressive threats to sometimes fatal physical aggression between members of rival groups. Certain socio-ecological conditions, such as when resources are highly defensible and the relative power between the opposing groups is great, increase the likelihood of conflict (Enquist and Leimar 1990; Jaeggi et al. 2016). Aggressive intergroup conflict has been well documented in

primates (Majolo et al. 2016), in particular in chimpanzees where it is characterized by coalitionary attacks that involve apparently deliberate attempts to injure and kill the opponent (Glowacki et al. 2017; Manson and Wrangham 1991). The term “lethal raiding” refers to such unprovoked gang attacks on strongly outnumbered or isolated members of neighboring chimpanzee communities (Manson and Wrangham 1991). While the term is often associated with groups of chimpanzees making deep incursions into neighboring territories, often by stealth, this pattern of coalitionary intergroup aggression also occurs in the context of territorial boundary patrols as well as opportunistically, during chance intergroup encounters (Watts et al. 2006).

Chimpanzee Social Organization

Several features of chimpanzee social organization are thought to be related to the occurrence of lethal raiding, and so we first outline some of these aspects before providing descriptions and explanations of raiding behavior. Within chimpanzee groups, competition for access to food resources may be high at certain times of the year; however, fission-fusion dynamics allow individuals to respond adaptively to environmental variability. As a result, members of a chimpanzee community rarely gather together in a single, cohesive group, but rather travel, forage, and rest in subgroups, or “parties” that change in size and composition throughout the day in response to fluctuations in local resource availability (Wilson 2013). Typically, male chimpanzees remain a member of their natal group throughout their lives, a feature known as male philopatry, whereas female chimpanzees disperse from their natal group when they reach sexual maturity (e.g., Boesch et al. 2008; Pusey 1980). In chimpanzees, as in other primates, male philopatry is associated with remarkable levels of male-male cooperation (Boesch et al. 2008; Manson and Wrangham 1991), and male mating success may be increased through coalitions with other males (e.g., Watts 1998). Because, in most mammals, male fitness is primarily determined by access to fertile females,

while female fitness is largely determined by access to resources (Davies et al. 2012), chimpanzee males can maximize their fitness by defending a territory containing valuable food resources which increase the reproductive success of the females within the community and may attract additional females (Pandit et al. 2016). As chimpanzee males mate with multiple females and females mate with multiple males, this is known as resource defense polygynandry. Fission-fusion dynamics, male philopatry, and resource defense polygynandry are inherent to chimpanzee sociality and are crucial to understanding how and why lethal raiding occurs in this species.

Patterns of Lethal Raiding in Chimpanzees

Observations of Lethal Raiding

Intercommunity killings are mainly observed when large parties, consisting mostly of adult males, encounter isolated and/or greatly outnumbered individuals (Manson and Wrangham 1991; Wilson et al. 2014; Wrangham 1999). The most common context in which this occurs is during territorial boundary patrols into areas of range overlap with neighboring communities (Manson and Wrangham 1991; Watts et al. 2006). During these patrols, the males move cautiously and quietly, often in single file, stopping to listen intently and/or inspect signs of outgroup chimpanzees such as feces, nests, and discarded food wadges (Boesch and Boesch-Achermann 2000; Wilson 2013; Wrangham 1999). If the males encounter members of the neighboring community, their response depends on the size and composition of this outgroup party. Lethal intercommunity attacks most often occur when the attackers greatly outnumber their opponent, with a median ratio of eight to one (Wilson et al. 2014). If the encountered party contains two or more males, the raiders will typically retreat (Manson and Wrangham 1991). However, an isolated male, sexually unreceptive female, consorting male-female pair, or an infant may be stalked and attacked. Sexually receptive females without infants are potential immigrants and therefore

less likely to be aggressed by the raiding party (Boesch and Boesch-Achermann 2000; Pusey 1980). The targeted individual is often restrained or immobilized by the superior numbers of attackers, enabling the attackers to inflict potentially lethal injuries with little to no risk to themselves (Boesch et al. 2008; Manson and Wrangham 1991; Wilson et al. 2014). In fact, there are no reports of attacking parties suffering any major injuries (Manson and Wrangham 1991; Pandit et al. 2016). If members of the neighboring community are not found, the party may either return to their territory or penetrate deeper into the neighboring range (Manson and Wrangham 1991).

Intergroup killings also occur opportunistically, for example, during chance encounters between hunting or foraging parties, often after auditory contact (Boesch et al. 2008; Watts et al. 2006). The frequency of such chance encounters can be affected by food distribution, as observed in Kanyawara (Uganda) where chimpanzees spent more time near the southern border of their territory when fruits there were ripe (Wilson et al. 2012). The majority of observed intergroup interactions occurred during this seasonal fruit availability, likely because chimpanzees from different communities were attracted to the same area and ranges overlapped simultaneously (Wilson et al. 2012). Upon making auditory contact with members from a neighboring community, chimpanzees may silently approach them, after which the encounter follows a similar pattern to those that arose during boundary patrols. Regardless of whether the attack results from a patrol or chance encounter, once the victim is isolated, attackers often persist until the individual is dead, after which they may continue to drag, hit, kick, and jump on the body (Wilson 2013). Should the victim attempt to escape during the attack, the attackers may give chase and attempt to restrain them and/or inflict further harm (Watts et al. 2006). Inspection of the bodies reveals that male victims are frequently emasculated during the attack by removal of the testes and/or penis (Boesch et al. 2008; Watts et al. 2006). Attackers sometimes twist limbs, inflict wounds with their canines, remove extremities and appendages such

as fingernails and ears, and rip off strips of flesh (Watts et al. 2006; Wilson 2013). There are also many documented cases of intercommunity infanticide, following attacks on neighboring females with dependent offspring, after which the infant is often cannibalized (Boesch et al. 2008).

If, during an attack, auditory contact is made with nearby members from the attacked individual's community, the attackers may become wary of these potential supporters and retreat before killing the targeted individual (Watts et al. 2002, 2006). In these cases, the victim may still die in the following days, most likely from internal injuries (Watts et al. 2006).

Frequency of Lethal Raiding

Observations of lethal raiding in chimpanzees all come from long-term study sites (e.g., Gombe and Mahale in Tanzania), as the large ranges and low population densities of chimpanzees make intergroup encounters relatively infrequent (Wilson 2013). In more densely populated areas, such as Taï Forest (Côte d'Ivoire) and Ngogo (Uganda), encounters between communities occur around once or twice per month (Boesch et al. 2008; Wilson 2013).

The majority of intergroup interactions are limited to acoustic contact, where members of neighboring communities remain separated by hundreds of meters (Boesch et al. 2008; Wilson 2013). Chimpanzees use long-distance vocalizations, such as pant-hoots, to communicate with members of their community (Goodall 1986). When hearing calls from another community, chimpanzees might respond with their own chorus of pant-hoots (Watts et al. 2006; Wilson 2013). In some cases, however, the chimpanzees remain silent and either stay still, looking in the direction of the vocalization, rapidly retreat, or move toward the callers, potentially escalating the interaction to visual contact which, depending on the size and composition of the encountered party, could in turn escalate to physical contact, often leading to injuries or death (Wilson 2013). Most intergroup interactions are limited to acoustic contact. In the Taï Forest, for instance, only 27% of intergroup encounters included visual contact, of which 1.5% (0.4% of all intergroup encounters)

involved lethal aggression (Boesch et al. 2008; Wilson 2013).

Just over a third of all lethal aggression between chimpanzees occurs during aggression within communities (37%), while the remaining two-thirds occur (63%) during intergroup aggression (Wilson et al. 2014). The higher percentage of intergroup fatalities becomes even more prominent when the frequency of contact is considered. In theory, chimpanzees have the opportunity to lethally attack members of their own community every day, yet only rarely encounter members from other communities (Wilson et al. 2014). The two types of lethal aggression are also distinct in that most intragroup killings are infanticides, whereas lethal intergroup aggression often targets adults (Wrangham et al. 2006). Though relatively rare, intraspecific killing (including intragroup aggression) is a highly significant cause of death in chimpanzees, second only to dying from disease (Williams et al. 2008). When taking the low population sizes and observation times into account, a study of nine chimpanzee communities estimated that intraspecific aggression caused 271 deaths per 100,000 individuals per year (69 deaths per 100,000 individuals per year from intergroup aggression alone) (Wilson 2013; Wrangham et al. 2006). To put these numbers into perspective, the rate of intentional homicides in the United States in 2016 was 5.35 deaths per 100,000 individuals per year ("UNODC Statistics Online" n.d.). The relatively high percentage of intergroup fatalities, combined with the brutal and perseverant nature of the attacks, suggests that the killing of adult opponents is characteristic to chimpanzee intergroup conflict, rather than merely a consequence of escalated resource competition. If so, chimpanzee raiding shares one of the most important distinguishing characteristics of human intergroup aggression and warfare: the deliberate killing of conspecifics (Manson and Wrangham 1991).

Adaptive Explanations

In order for a behavioral strategy to be adaptive and evolve, the benefits of performing the

behavior must outweigh any potential costs to the animal, leading to an increase in reproductive success, that is, an increase in the number of direct and/or indirect descendants (Davies et al. 2012; Wilson 2013). It is difficult to test and evaluate the adaptive benefits of lethal intergroup aggression in chimpanzees, due to their relatively slow life histories (Watts et al. 2006). There are several adaptive hypotheses in the literature that offer explanations for lethal raiding in chimpanzees, and while they all share the ultimate function of increased fitness through greater access to resources and/or reproductive females, they differ in their emphasis on the proximate mechanisms and socio-ecological conditions that elicit lethal aggression. These explanations are not mutually exclusive and a combination of factors likely selects for lethal raiding (Watts et al. 2006; Wilson 2013).

Resource Defense Hypothesis

The resource defense hypothesis (Emlen and Oring 1977) suggests that intergroup aggression benefits the attacking community by allowing them to defend food resources, which, due to resource defense polygyny in chimpanzees, affect both the males' access to females and the reproductive success of these females, and therefore the fitness of the defending males (Williams et al. 2004). Performing raids in a particular area might induce the targeted community to avoid using that area and/or its resources (Pandit et al. 2016). This hypothesis is consistent with an observed increase in patrol frequencies with the availability of ripe fruit (Watts et al. 2006). Additionally, the resource acquisition hypothesis suggests that chimpanzees attack other groups, not just to defend their resources but to further expand their territories, gain access to more food, increase the feeding success of their community, and therefore potentially increase female reproduction (Mitani et al. 2010; Williams et al. 2004; Wrangham 1999). This is supported by observations of coalitionary attacks on a neighboring group, followed by territorial expansion into areas previously occupied by that group (Mitani et al. 2010). The resource defense hypothesis broadly explains the reproductive benefits of

intergroup conflict in chimpanzees, predicting that male philopatry should arise as a consequence of resource defense (Greenwood 1980; Ostfeld 1987). It can therefore provide the socio-ecological context in which male-driven lethal intergroup aggression is expected (Jaeggi et al. 2016; Pandit et al. 2016). It has been suggested that, while resource defense polygyny explains the reproductive benefits of intergroup conflict in chimpanzees, it is insufficient to explain why chimpanzee raiding appears to be aimed at killing their opponent, rather than merely displacing them from the contested area (Pandit et al. 2016). If so, lethal intergroup aggression in chimpanzees must be promoted by additional factors, as suggested by the fact that this behavior is not commonly reported in other primate species with a resource defense mating system (Pandit et al. 2016).

Imbalance of Power Hypothesis

Currently, one of the most widely accepted explanations for the lethal intergroup aggression in chimpanzees builds on this prior explanation of resource defense polygyny, to suggest that the behavior is promoted by their fission-fusion sociality and male philopatry, which create opportunities for intergroup encounters where one party has a superior number of cooperating males (Glowacki et al. 2017; Manson and Wrangham 1991; Pandit et al. 2016; Watts et al. 2006). By nature of numerical superiority, attackers can greatly reduce the costs of aggression (risk of injury) and more easily inflict injury on others. An important factor in this risk reduction is the cooperative, coordinated nature of the attacks, facilitated by coalitionary bonds between philopatric males, in which opponents are quickly subdued or immobilized, further minimizing potential costs (Manson and Wrangham 1991; Watts et al. 2006). The "imbalance of power hypothesis" therefore proposes that lethal attacks are promoted not by high benefits but primarily by low costs (Manson and Wrangham 1991; Wilson et al. 2014). Despite acknowledging the substantial benefits of lethal raiding, Manson and Wrangham (1991) highlight the fact that there is only one confirmed, and one suspected, case of

group extinction due to lethal raiding. They therefore conclude that the benefits, while potentially great, are likely to be much less important than the costs when considering the evolution of lethal raiding behavior. The hypothesis has been well-supported by observations that most lethal intergroup aggression occurs when large parties attack a greatly outnumbered individual and by the fact that there are no reports of major injuries incurred by the attackers (Manson and Wrangham 1991; Pandit et al. 2016).

It must be stated that, while most intergroup aggression has been observed to occur in low-cost situations, chimpanzees sometimes appear to accept large risks and engage in conflict with numerically superior communities, even when in very small parties (Boesch et al. 2008). In these cases, social factors, such as limited access to fertile females, may increase the potential benefits of attacking (or the cost of inaction) to exceed the potential cost of attacking, even without a favorable imbalance of power (Boesch et al. 2008).

Reduce Rivals Hypothesis

The benefits of killing an opponent, rather than chasing them off, could simply be to eliminate a potential competitor or reduce the coalitionary strength of the rival group (Boesch et al. 2008; Mitani et al. 2010; Watts et al. 2006; Wilson 2013; Wilson et al. 2014; Wrangham 1999). This “rival coalition reduction hypothesis,” also called the “dominance drive hypothesis,” is strongly linked to the imbalance of power hypothesis. The benefits of killing a rival hold true for any species with group-level conflict (Wilson et al. 2014). However, in species without a mechanism to facilitate a sufficient imbalance of power, this benefit is likely outweighed by the potential cost of killing (Wilson et al. 2014). In these cases, animals would likely not risk injury by pursuing and attempting to kill their opponent but would simply displace them from the contested resource (Wilson 2013). Enabled by the fission-fusion social system, gang attacks and lethal raids provide low-cost opportunities for chimpanzees to decrease a neighboring community’s competitive ability (Wrangham 1999). As males do not migrate between groups, killing a male reduces the coalitionary strength of

the targeted community until the male is replaced through births within that community (Wrangham 1999).

Female Recruitment Hypothesis

It has also been suggested that intergroup attacks serve to recruit new females, as young females have been observed to join the attacking community (Goodall 1986). Though this hypothesis has not yet been systematically tested, there are indications that emigrating females may select communities with large numbers of adult males, so these attacks could serve to advertise their community size (Boesch et al. 2008; Wilson 2013). The observed intergroup infanticides have also been suggested to be a strategy to increase males’ access to fertile females, as is the case in species such as lions, langurs, and gorillas (Boesch et al. 2008). However, there is currently no convincing evidence this behavior increases the likelihood of female chimpanzees joining the infanticidal males’ community (Boesch et al. 2008). As stated before, the proposed adaptive explanations are not mutually exclusive. Males may be able to attract new females by defending and expanding their resources (Manson and Wrangham 1991; Pandit et al. 2016). This territorial expanse could in turn be facilitated by the reduction of the rival coalitionary strength (Mitani et al. 2010; Watts et al. 2006), which is made strategically viable through the imbalance of power.

Female-Targeted Attacks

If chimpanzee raiding is a strategy by which coalitions of chimpanzee males are able to decrease the coalitionary strength of males from neighboring communities, as per the rival reduction hypothesis, this raises the question of why these attacks have also been observed to target adult females (see Marchant and McGrew commenting in Manson and Wrangham 1991). While female involvement in intergroup conflict has been observed to vary between populations, the killing of adult females also occurs in populations where females do not actively participate and is therefore not sufficiently explained by the rival reduction hypothesis (Boesch et al. 2008; Watts et al. 2006).

Furthermore, the female recruitment hypothesis proposes that lethal raiding benefits participating males via the recruitment of potential reproductive partners. This hypothesis would therefore predict that males would not target adult, sexually receptive females, but would rather predict attempts at affiliative behavior (Boesch et al. 2008; Watts et al. 2006; Wilson and Wrangham 2003). At Gombe, attacks on sexually receptive females were observed to occur less often than attacks on non-receptive females, but the question remains as to why females are attacked at all (Williams et al. 2004).

One possibility is that attacks on females may serve to weaken bonds between adolescent females and their mothers to induce the younger females to transfer communities and thus benefit the recruitment of females (Goodall 1986). A second possibility is that infanticide of the female's infant is the primary goal (Hiraiwa-Hasegawa and Hasegawa 1994), and a third is that aggression elicits mating with the female (Boesch and Boesch-Achermann 2000). However, there appears to be little evidence for such transfer of females after attacks (females transfer at adolescence due to female dispersal anyway), targeting of infants or post-attack mating (Williams et al. 2004). Of the adaptive explanations for lethal intergroup aggression in chimpanzees covered in this text, only the resource defense hypothesis offers an explanation for attacking adult females as it may be a way for chimpanzees to further induce a neighboring community to limit their use of certain areas or resources (Wilson 2013). If so, the killing of sexually receptive outgroup females should occur in cases where the potential expansion of territory provides greater reproductive benefits than the recruitment of a potential reproductive partner.

Further insight, into conditions influencing whether males should attack females in neighboring communities, is provided by a model that incorporates the degree of reproductive skew among males (Pradhan et al. 2014). When the highest-ranking male has priority of access to females, the addition of neighboring females to his community (while increasing birth rate) increases the number of females that have

overlapping periods of sexual receptivity. This in turn decreases the level of skew, as the dominant male(s) can no longer monopolize all females. Thus, high-ranking males should prefer to expand their territory, attacking females rather than tolerating them, whereas lower-ranking males can gain greater fitness benefits by tolerating new females. As the reproductive skew decreases, mating success is more equally distributed across males, and therefore both high- and low-ranking males benefit from fatal attacks on females. Current observations provide initial support for this model, but further data are required to test predictions in detail.

Influence of Human Disturbance

Critics of the adaptive interpretation of chimpanzee intergroup aggression have suggested that killing is merely incidental to intergroup aggression, exacerbated by human influences such as human encroachment (deforestation, hunting, etc.) and food provisioning by researchers (Power 1991; Sussman and Marshack 2010; Watts et al. 2006).

Several aggressive, territorial behaviors, including boundary patrols and intergroup killing, were first observed at Gombe and Mahale, contrasting with earlier reports from short-term studies at other sites that seemed to indicate peaceful chimpanzee communities with open membership (Goodall 1977; Goodall et al. 1979; Nishida 1968, 1979; Reynolds and Reynolds 1965; van Lawick-Goodall 1968; Wilson 2013). The Gombe and Mahale sites both used artificial feeding to facilitate observations, raising the possibility that the intergroup aggression was caused by food provisioning, rather than being part of a natural behavior repertoire (Power 1991). It was shown that provisioning impacted the chimpanzees' behavior, with increased aggression on days that food was provided, though this impact might not have extended to behavior away from the feeding station (Wilson 2013; Wrangham 1974).

This "human impact hypothesis" further expanded to include other human influences that could cause or increase aggressive behavior.

Human encroachment or disturbance of habitat (e.g., the conversion of forest into cropland) could affect intergroup aggression by increasing competition for the space available (Goodall 1977; Pusey et al. 2007; Wilson 2013). Poaching and human-transmitted diseases could decrease coalition sizes within a community and leave them vulnerable to attack (Goodall 1977; Pusey et al. 2007; Wilson 2013). However, since then, data from sites that were habituated without food provisioning do not support this “human impact hypothesis” and show that observed variations in rates of lethal aggression in chimpanzees were not explained by either provisioning by researchers or any other measured indication of human disturbance (Wilson 2013; Wilson et al. 2014). In fact, the highest rate of killing was observed at Ngogo, an unprovisioned and relatively undisturbed site (see Richard Wrangham commentating in Sussman and Marshack 2010). Current studies not only support the adaptive explanation of lethal coalitionary aggression as part of an evolved behavioral strategy but also indicate that the rate at which this behavior occurs is unrelated to the suggested human influences (Watts et al. 2006; Wilson et al. 2014).

Relevance to Human Warfare

Adaptive explanations of chimpanzee raiding as a natural behavioral strategy are central to the debate on the origins of human warfare (Gat 2006; van der Dennen 1995; Wilson 2013). It is often cited as evidence against the argument that war is a relatively recent cultural invention, originating within the past 12,000 years (Ferguson 2011; Gat 2015; Otterbein 1999).

The imbalance of power hypothesis predicts that lethal coalitionary attacks should occur in species where intergroup conflict is beneficial to reproductive success, party sizes are variable (facilitated by fission-fusion sociality in chimpanzees), and individuals form long-term coalitionary bonds (Glowacki et al. 2017; Wrangham 1999; Wrangham and Glowacki 2012). Human hunter-gatherer societies generally display coalitionary bonding between males, a fission-fusion social

system, and may often have hostile relationships with neighboring communities (Glowacki et al. 2017; Heinz 1972; Wrangham 1999; Wrangham and Glowacki 2012). Hunter-gatherer conflict often involves low-risk, coalitionary attacks on strongly outnumbered members of a rival community (Glowacki et al. 2017). These raids are performed by groups of men, who leave their territory with the intent to ambush, or otherwise surprise, small groups (Gat 1999), after which, the raiders quickly retreat to their own territory (Glowacki et al. 2017). They are relatively low-risk to the raiding party, though some injuries can occur (Chagnon 1997; Glowacki et al. 2017). Intergroup conflict appears to allow these male coalitions to defend and increase resources (e.g., territory and food) crucial to their reproductive success, as is thought to be the case for chimpanzees (Wilson 2013; Wrangham and Glowacki 2012).

Despite these similarities, several key differences distinguish raiding behavior in humans and chimpanzees. The use of weaponry, such as bows, clubs, and spears, introduces an unpredictability to the imbalance of power and therefore affects the potential cost of lethal raiding (Boesch et al. 2008; Kelly 2005). During surprise attacks on unarmed individuals, weaponry can greatly amplify the difference in instantaneous fighting ability and further reduce the cost of killing (Pandit et al. 2016). However, if an attacked individual also has access to weapons, they may seriously injure or kill members of the attacking coalition (Glowacki et al. 2017; Kelly 2005), greatly increasing the cost relative to chimpanzee raiding. Humans can also affect the imbalance of power through the strategic use of terrain, deception, and other relatively complex tactics (Wadley 2003).

The origin of human warfare is too complex to determine from chimpanzee data alone, but the similarities between the two species support the view that warfare in humans is a behavioral strategy by which coalitions of males increase their fitness as a result of defending and expanding relevant resources (Glowacki et al. 2017; Wilson 2013). War is likely not caused by a single instinct but is facilitated by several evolved psychological traits, such as xenophobia and parochial altruism

(Glowacki et al. 2017). As a result, the frequency and methods of warfare are heavily influenced by cultural differences, technological advances, and political and economic relations. Unlike chimpanzees, who can only benefit from intergroup interactions at the expense of the other party (e.g., by taking over parts of their territory), human intergroup interactions are not always a zero-sum game (Wilson 2013). Humans can trade with neighboring groups as an alternative, peaceful strategy to obtain their resources with a potentially lower cost than warfare.

It is important, therefore, to emphasize that the possibility of a biological basis for warfare in humans does not mean that this behavior is inevitable or even justifiable (Glowacki et al. 2017; Wilson 2013). There is no reason to believe that warfare cannot be reduced or even eliminated (Glowacki et al. 2017). Whether it is cultural or biological in nature, intergroup aggression is only a viable strategy if the benefits outweigh the costs. Throughout history, political institutions have increased the cost of violence and facilitated peaceful interactions within a certain region (e.g., a nation) and pushed warfare to the borders of that region (Glowacki et al. 2017). These zones of peace have expanded from small regions of allied communities to the borders of a single nation to large regions of friendly nations, such as the European Union. By expanding such regions in which the costs of warfare and/or the benefits of peaceful, mutually beneficial interactions are increased, global peace could be a practically achievable goal.

Conclusion

Current evidence indicates that the coalitionary killing of intergroup conspecifics in chimpanzees is an adaptive behavior facilitated by fission-fusion dynamics, resource defense polygyny, and male philopatry. The adaptive explanations presented in this text are not mutually exclusive and a combination of factors are likely to interact. For instance, fission-fusion dynamics and male philopatry create

opportunities in which the imbalance of power is such that coalitions of males are able to kill members from other communities with little to no risk of incurring serious injuries. The imbalance of power therefore makes it strategically viable for chimpanzee males to reduce the coalitionary strength of a neighboring group. This could be necessary for territorial expansion (Mitani et al. 2010; Watts et al. 2006), which, in turn, could increase their access to fertile females (Manson and Wrangham 1991). Contrary to the human disturbance hypotheses, lethal aggression in chimpanzees appears to be part of their naturally evolved behavioral repertoire. While raiding in human hunter-gatherer societies may have had a similar adaptive function, there is no reason to believe that warfare in humans is unavoidable.

Chimpanzee Sexuality

Emily E. B. Boehm and Kara K. Walker
Evolutionary Anthropology, Duke University,
Durham, NC, USA

Chimpanzees (*Pan troglodytes*) are highly intelligent animals whose sexual behaviors occur in the context of a complex social environment: Chimpanzees live in multi-male, multi-female communities that can range in size from <10 to approximately 200 members. These communities exhibit a fission-fusion dynamic, where all community members are rarely, if ever, together at the same time; instead, individuals range and forage in fluid sub-groups whose composition changes over the course of hours or days (Goodall 1986; Nishida 2012). Males and females compete for rank in separate linear dominance hierarchies; all adult males are dominant to all adult females (Hayaki et al. 1989; Takahata 1990; Pusey et al. 1997; Muller 2002). Mating is promiscuous, paternity certainty is low, and there is no evidence of direct paternal care (Goodall 1986). Because infanticide by males is sometimes observed, promiscuous mating is most often interpreted as a female strategy to decrease paternity certainty and avoid infanticide.

Female sexuality in chimpanzees is characterized by swelling of a specialized anogenital sexual skin for a portion of the ~35-day ovarian cycle, which is also associated with behavioral estrus (Tutin 1979; Goodall 1986). Full swelling lasts for an average of 12–13 days but can vary with age and among populations (Wallis 1997;

Deschner et al. 2003; Matsumoto-Oda et al. 2007; Thompson 2013). These swellings are hormonally mediated: rising estrogen during the follicular phase leads to tumescence, while detumescence is triggered by progesterone in the luteal phase, following ovulation (Graham 1981; Dixson 1983).

Young females typically exhibit their first swelling around age 8, but these initial swellings are small and do not elicit attention or mating from adult males (Pusey 1990). Females are considered sexually mature upon their first mating with an adult male. However, they may then experience a period of adolescent sterility, cycling and mating for a period of years before conceiving. Juvenile and even infant males may play thrust and mount toward their peers and estrous females. Males show marked testicular growth and began ejaculating around age 9 but do not typically sire offspring until they are at least 12 years old (Pusey 1990).

In parous females, swelling resumes after a period of post-partum amenorrhea. Females are most attractive to males and receptive to mating during maximum tumescence, which corresponds approximately to the periovulatory period (Deschner et al. 2003, 2004; Emery and Whitten 2003; Emery Thompson 2005). Successive swellings tend to increase in size approaching conception, and males are also sensitive to this inter-cycle variation, mating more during the conception cycle (Deschner et al. 2004; Emery Thompson and Wrangham 2008). Female attractiveness increases with both age and parity, suggesting that males are most attracted to females with proven records of maternal care (Muller et al. 2006). High-ranking males are most likely to mate when the chance of conception is highest, while females may use proceptive behaviors outside of the periovulatory period to secure mating opportunities with lower-ranking, younger males and avoid monopolization by the alpha (Nunn 1999; Stumpf and Boesch 2006). Post-conception swellings may also occur, most frequently early in gestation, and females may mate during these swellings, but their functional significance is poorly understood (Wallis and Lemmon 1986; Wallis and Goodall 1993).

Female proceptive behaviors include grooming with males and presenting their swelling for inspection. Males inspect sexual skins, both swollen and non-swollen, by directly sniffing or by sniffing a finger that has been inserted into the vulva (Nishida 1997). These inspections may allow males to assess the fertility of a given female (Wallis 1992). Females may occasionally display proceptive behaviors more typical of males, such as a branch-shaking, to attract the attention of a desired mate (personal observation).

Males use a variety of courtship behaviors to solicit matings from sexually receptive females, including shaking branches, bipedal walking, piloerection, stomping or pounding on the ground or tree roots, and penile displays, which consist of the presentation of the erect penis, often in combination with a flicking motion (Goodall 1986). Copulation occurs with the male squatting behind the female, who crouches and lifts her swelling to facilitate intromission. Males may also use aggressive coercion, both at the time of mating and during non-swollen periods, to increase their mating success (Muller et al. 2007, 2010; Feldblum et al. 2014). Forced copulation has also been recorded (Goodall 1986). Males may attempt to restrict other males from mating by interfering in copulations or aggressively mate guarding an estrous female when the pair is in a larger group (Wroblewski et al. 2009). In a more extreme manifestation of mate guarding, pairs can also form consortships, leaving the group to range alone for a period of hours to months (Tutin 1979). Consortships lead to exclusive mating by one male and, as such, are often resisted by females, who may be aggressively coerced into leaving the group with a single male. Alpha males have the highest reproductive success during their tenures, but lower-ranking males sire a larger-than-expected proportion of offspring, suggesting that alternative strategies such as consortships and sneak copulations are also effective (Wroblewski et al. 2009). Because females often mate with most or all community males during a single cycle, sperm competition is high, and males have relatively large testicles (Tutin and McGinnis 1981; Hasegawa and Hiraiwa-Hasegawa 1990).

Chimpanzee sexuality is perhaps best understood as a set of male strategies for monopolizing females and the counter-strategies used by females to avoid monopolization. New lines of evidence add nuance to this picture, suggesting that females are more likely to conceive with unrelated males and that sires may recognize and bias behavior toward their own offspring.

Definition

The increased prevalence of mistreatment, both lethal and nonlethal, of children by a biologically unrelated step-parent, compared to by a genetically related parent.

Introduction

Cross culturally, folklore and fairytales have portrayed step-parents as menacing and potentially life threatening to their unrelated offspring. Over the last 30 years, a body of literature has demonstrated that this portrayal is, in fact, reflected in the real world as a significantly increased risk for the child of an unrelated parent to be a victim to child abuse and homicide, a phenomenon referred to the *Cinderella Effect* (Daly and Wilson 1999). An evolutionary explanation of this fictional phenomenon, based on kin selection theory (Hamilton 1964) and the subsequent Hamilton's Rule, predicts that a lack of shared genes between a step-child and parent will discourage altruistic behavior and investment in this offspring.

Child Abuse

Kin selection theory is based on the idea that individuals having shared genes are more likely to invest in one another and display altruistic behaviors. For example, parents sharing the same genes as their biological children are more likely to interact with them in a healthy and positive manner. It should be expected that step-relationships would experience this same need to build relationships between one another. However, research has consistently found that these step-relationships involve less investment (by step-parents), tend to be more conflictual, and are less satisfying compared to the relationships between genetic parents and children (Wilson and Daly 1987). Step-parents are less likely to experience the need to invest in their step-children because they do not share the same genes. They tend to prefer their own biological children in any given situation. According to Daly and Wilson (1988), “genetic relatedness is a predictor of reduced conflict and enhanced cooperation because the genetic posterities of blood relatives covary (are promoted by common exigencies) in direct proportion to their degree of relatedness” (p. 519).

Violence towards non-kin, depends as evaluated through the occurrence of physical child abuse, exemplifies the discrepancy between kin-driven altruism for related and unrelated parents. Using over 20,000 reports of child abuse from the American Humane Association, Daly and Wilson found that “a child under three years of age who lived with one genetic parent and one stepparent in the United States in 1976 was about seven times more likely to become a validated child-abuse case in the records than one who dwelt with two genetic parents” (Daly and Wilson 1999, p. 27). This finding was further supported through research on child abuse in Canada, England, Sweden, and Korea, all of which provide evidence for trends of increased likelihood of abuse at the hands of a step-parent (1999).

Infanticide

Based on Hamilton’s Law, investment in a genetically unrelated offspring involves high costs, without associated inclusive fitness benefits. Those costs additionally create direct competition with the prospects and resource access for one’s own (genetically related) offspring. In some cases this can lead to the killing of an infant, or infanticide, which has been documented in both human and nonhuman contexts. A male African Lion, for instance, upon gaining access to a pride of potential female mates, will kill the female mate’s previous offspring. This behavior promotes the reproductive success and efficiency of their own reproduction.

The prevalence of infanticide among non-related parents and offspring has been evaluated in humans as well, with research finding that it is significantly more likely to occur when parent and offspring are unrelated. An early study of the homicide of infants in England, finding that a significant (and disproportionate to the general population) number of these killings was in fact committed by step-fathers (Scott 1973). This trend was more broadly supported by Daly and Wilson (1988), who found that

coresiding step-parents were about 70 times more likely to kill a child under two, compared than a genetic parent.

There are also other aspects influencing rates of infanticide: the mother’s age and marital status. According to the hypothesis proposed by Daly and Wilson (1988), younger women are more likely to engage in infanticide compared to older women. Burgos and McCarthy (1984) found that women (ages 15–19) were more likely to commit infanticide among the Ayoero Indians. Daly and Wilson (1988) also found similar findings in Canada; infanticide was more frequent among younger women. Marital status also influences the rates of infanticide. Women that were not married were less likely to deliver babies (approximately 12%), but they also accounted for a higher percentage of reported infanticides (Daly and Wilson 1988). Both of these variables interact with each other; younger women that are unwed are most likely to commit infanticide.

Discriminative Parental Solitude

Ornithologist Harry Power (1975) found that nonrelated Mountain Bluebird males would differentially refuse to feed the prior offspring of their mates, for which there was a discrepancy between parental investment based on the amount of shared genes. This selective investment can have similar consequences in the dynamics of human step-families, creating sentiments of less love and affection from both the step-child and step-parent, as well as a higher rate of conflict within the marriage over issues of children and resources.

These issues do not stem from the desire of step-parents to intentionally harm their step-children, according to Daly and Wilson. As mentioned above, step-relationships are less likely to have the same levels of affection and commitments as genetically related relationships (Wilson and Daly 1987; Doberman 1998). Step-parents also are less likely to experience the same type of emotions regarding unreciprocated

parental investment compared to genetically related parents (Daly and Wilson 1996). For example, these differences could contribute to explanations as to why step-parents may react violently toward step-children; the emotional barriers to violence are less strong.

Circumventing Mate Choice

Ashleigh J. Kelly

School of Psychology, The University of Queensland, St Lucia, Brisbane, QLD, Australia

Synonyms

Mate guarding; Mate rejection; Mating sabotage; Relationship dissolution; Romantic rejection; Sexual rejection; Stalking

Definition

Disregarding or obstructing the sexual or romantic decisions of others or disregarding one's own previous mating decisions

Introduction

Mate choices fall into several different categories. One can choose a partner for sexual relations only, for a short-term non-committed liaison, for a short-term committed relationship, or for a long-term uncommitted or committed relationship. When an individual makes an overture to form or continue a relationship, the other can choose whether to accept or reject them for the proposed interactions, and an outsider can interfere with the process. Kelly et al. (2016) suggested that all the behaviors seen within human mating contexts could be classified along a continuum. The proposed spectrum ranged from active rejection (purposefully preventing mating attempts), followed by indifferent rejection (e.g., not selecting a partner), then mate selection (selecting and obtaining a

partner), and finally to mate retention (retaining the partner). The act of circumventing mate choice can occur at any of these relationship stages, including within existing or established relationships or during the first advances. It can involve denying mating attempts by a potential or actual partner or obstructing the attempts of peers, kin, partners, or a desired individual to mate with others.

Circumventing Mate Choice in Early Courtship

Mate rejection is easier in the early courtship phases, prior to a relationship being established (discussed in Kelly et al. 2016). At this time, one can circumvent the mate choices of others by simply denying potential partners access to their time or body (including their friendship or companionship), thereby circumventing sexual or romantic advances. Methods used to circumvent mate choice at this stage might involve avoidance, verbal rejection, physically stopping mating attempts (e.g., pushing, kicking, punching, assuming a fetal position), threats (similar to those seen in Kelly et al. 2015), and taking refuge among friends or family (discussed in Smuts 1992; for full discussion of potential mating avoidance strategies, see Duntley and Shackelford 2012).

On the flip side, a potential suitor might circumvent the mate choices of their target mate by obstructing the target's attempts to partner with someone else. In this situation, the perpetrator might use methods that include stalking, intimidation, and threats in an effort to isolate and coerce their chosen mate into a relationship or liaison (see discussion in Duntley and Buss 2012).

Parents, family, and friends can also circumvent mate choices, by disallowing their kin or friend to become sexually active or partnered with an individual that they deem inappropriate (Perilloux et al. 2008; discussed in Duntley and Buss 2012; see also Smuts 1992). The methods used by kin in these early stages can be physical (e.g., chaperoning or disallowing one-on-one contact, physically attacking the suitor), verbal (e.g.,

threats), and social (e.g., shaming or damaging the social standing of the suitor).

Circumventing Mate Choice in Existing Relationships

Circumventing mate choice is still possible even after mating decisions have been made: from the moment the relationship is established to within a deeply committed long-term relationship. Within a relationship, one partner can circumvent the mate choice of the other simply by denying copulation. Here, even though a mate choice has been accepted (by entering the relationship), a partner can still exercise control over his or her own mating and potential conception.

Terminating the relationship would also circumvent a previously established mate choice and can lead to genuine evolutionary challenges for the rejected party (Perilloux and Buss 2008) as well as the rejecter (Kelly et al. 2015; see also Kelly et al. 2016). Furthermore, established partners may circumvent their previous mate choice by remaining in a relationship yet engaging in extra-pair mating (e.g., infidelity). In this way, an individual can disregard their partner and any commitment of exclusivity they may have made to them and obtain additional sexual or romantic companions.

In response to this threat, couples may restrict the extra-pair mating attempts of their partner by engaging in various mate retention strategies. As established by Buss (1988; see also Miner and Shackelford 2010; McKibbin et al. 2007), these strategies might include positive approaches like kindness, helpfulness, and gift giving or unsocial strategies including exercising physical control (e.g., using violence) and emotional control (e.g., using threats or belittling the partner's self-esteem so that they will not seek alternate mates) or controlling their partner's time (e.g., booking out their schedule so that they cannot be apart or able to stray). Mate guards might even stalk their partner (e.g., following them, monitoring their social and online interactions; see discussion in Duntley and Buss 2012). Using these techniques, one partner might circumvent the

extra-pair mate choices of the other by restricting their ability to acquire another mate, gain access to that mate, or copulate with them.

Conclusion

It is possible to circumvent the mate choices of others in many different ways. One can avoid the advances of both potential and actual mates and can block the attempts made by peers, kin, or a desired entity to mate with others. One can even circumvent their own mating choices by engaging in mate rejection or extra-pair mating. The partners of these individuals might try to prevent their mate from leaving or cheating by engaging in various mate retention strategies, thereby circumventing their partner's new mate choices.

Synonyms

[Civic commitment](#); [Civic engagement](#); [Civic involvement](#); [Civic obligation](#); [Civic participation](#); [Civic responsibility](#); [Community interest](#); [Community involvement](#); [Community participation](#); [Political interest](#); [Social responsibility](#)

Definition

Social norms that produce a feeling of obligation to provide help or to grant the requests of others in the belief that the common good is thereby served; an action or responsibility expected of every member of a society.

In a society or community, in order to establish the well-being of their surroundings, people tend to act not only to pursue personal interests but also to pursue collective interests shared by the whole group. Generally accepted examples of civic duty include obeying laws, serving on juries, paying

taxes to the government, being active about politics, voting in elections, and doing volunteer work. Individuals with greater sense of civic duty tend to exhibit more civic participation and activities.

The Socialization of Civic Duty

According to political socialization theory (Steintrager 1968), which tries to explain how, when, and through what agencies individuals learn their political behavior, family constitutes one of the most important agencies regarding the establishment of individual's civic duty. Parents pass on the content and meaning of civic duty to their offspring through behaviors and discussions in the regular life. Children learn about the civic participation by observing their parents' actual engagement in civic activities and by listening to what they are talking about politics and current events (Zaff et al. 2010).

Political socialization can be regarded as a replication model in which adolescents simply copy norms and understandings of civic duty from the former generation. Research supported the frequency of parent-adolescent political discussions which could powerfully predict adolescents' civic involvement. For example, with a sample of 5579 adolescents coming from 7 countries, the study (Flanagan et al. 1998) indicated that family socialization on social responsibility could produce a significant effect on adolescents' public interest. Another study found that individuals growing up in homes where they discussed current events with their parents and saw parents taking part in civic activities tended to engage more in political activities (Brady et al. 1995).

However, some researchers argued this theory ignored the impact of ecological environment, which influenced the forming of adolescents' opinions and active role in interpreting the given rules (Zaff et al. 2010). Consist with this opinion, recent studies found mothers' observed civic duty information in terms of following the rules and obeying laws correlated negatively with adolescents' attitudes on engaging in social movement activities. This result supported the active role of

adolescents' in the political socialization (Oosterhoff and Metzger 2016).

In fact, developmental systems theories, which emphasize the collective contribution of genes, environment, and epigenetic factors on developmental processes, proposed that there was an interaction between adolescents' behaviors and beliefs about civic duty and their ecological context. Adolescents' opinions about civic duty are plastic, which could be shaped or modified by the experience or information they receive from the environment.

This viewpoint has been supported by quite a few studies. In addition to parents, discussion with peers or teachers on politics and social events could produce significant effects on adolescents' civic behaviors, attitudes, and skills (Andolina et al. 2003). And peers may shape each other's civic duty beliefs by exchanging thoughts and sharing civic experiences (Oosterhoff and Metzger 2016). Actually the influence coming from the environment could be explained in terms of the power of social norms. Research (Flanagan et al. 1998) indicated that in order to identify with peers, specific groups, and institutions, adolescents would take part in voluntary work and student solidarity at school.

Factors Influencing Individual's Civic Participation

Individual's notion about civic duty is relatively stable, but the age effect is still obvious across the life span. High school students always exhibited a higher level of civic volunteering than young adults (Kirby et al. 2011). The level of civic engagement decreased generally in the transition out of high school (Malin et al. 2017), and civic participation among young adults was lower than other age groups (Twenge et al. 2012). The civic involvement would increase at roughly age 26 (Snell 2010).

In addition, due to the limitation of cognitive abilities, young person usually could not completely understand the abstract meanings of civic responsibility and the consequences of one's action on others' until the early adult years. Their

understanding of civic duty continues to increase throughout the whole life. Apart from cognitive abilities, age can also have indications for fulfilling civic engagement (Tsai et al. 2009). For example, problems that come along with aging can reduce the amount of social engagement. Depression, illiteracy, cognition impairment and other issues can all be risk factors of poor social engagement in old groups. Despite all this, researchers usually believe that higher levels of social engagement are associated with wellbeing and longer survival in the elderly (Kiely and Flacker 2003).

In addition to age, other demographic variables also contribute to individual's civic involvement, for instance, in comparison with people who didn't attend college, those who did demonstrated higher levels of civic involvement initially and over time. In addition, research (Flanagan et al. 1998) also demonstrated females were more likely than males to be engaged in voluntary work.

Conclusion

Family and peer norms play important roles in the formation of individual's civic duty. Across the life span, individuals would show different levels of civic involvement at different life stages.

Classical Conditioning

Christoforos Christoforou
University of Nicosia, Nicosia, Cyprus

Synonyms

[Associative learning](#); [Learning through associations](#); [Pavlovian conditioning](#); [Reflexive conditioning](#); [Respondent conditioning](#)

Definition

Classical and/or Pavlovian conditioning constitutes an automatic learning process that arises through the acquisition of an association between two stimuli. Through the acquisition of a classically conditioned association, a stimulus that prior to learning did not induce any particular response obtains the ability to induce a response that is qualitatively similar with the one that a biologically significant stimulus induces.

Introduction

Pavlovian and/or classical conditioning is a type of associative learning that involves the formation of new behavioral responses through the acquisition of new associations. Specifically, during the course of classical conditioning, an organism adjusts in response to the detection of sequential relationships between stimulus of environmental and/or proprioceptive nature (McSweeney and Murphy 2014). Classical conditioning has been discovered and methodologically described by a Russian physiologist named Ivan Petrovich Pavlov. This type of learning is named “conditioning” since its inventor, I. P. Pavlov, used the

term conditioned reflex to label and designate the learning outcome (Schachtman 2011). I. P. Pavlov assumed that new reflexive responses can be developed through the acquisition of classically conditioned associations between neutral stimuli, that is, stimuli which originally do not induce any particular response, and unconditioned stimuli, that is, biologically relevant stimuli which reflexively evoke an unconditioned response (Spence 1978). Through the acquisition of a classically conditioned association between a neutral stimulus and an unconditioned stimulus, the first turns into a conditioned stimulus and acquires the capacity to induce a conditioned response that is qualitatively similar to the unconditioned response (McSweeney and Murphy 2014). I. P. Pavlov examined various reflexes, yet his most widely known experiments revolved on responses to food. Even though early researchers in the fields of both human associative memory and behaviorism had studied mechanisms that nowadays would be considered to be similar to the ones that I. P. Pavlov described, I. P. Pavlov was the first who officially and methodologically described and designated the process of classical conditioning in the scientific community through the publication of conditioned reflexes in 1927 (Spence 1978).

The Study of Gastrointestinal System and its Role in Classical Conditioning

I. P. Pavlov discovered the associative mechanism of classical conditioning accidentally while examining the physiological processes of the gastrointestinal system. Specifically, I. P. Pavlov was examining the alternations of dogs' saliva and digestive fluid secretion through their mouth and stomach while feeding. At some point, during the experimental procedures that I. P. Pavlov set in order to observe the alternations of dogs' saliva and digestive fluid secretion in response to feeding, he observed that the subjects' (i.e., dogs) saliva and digestive fluid were also secreted every time he and his associates arrived in the laboratory. Consequently, I. P. Pavlov decided to experimentally examine the mechanisms and functional structures that let the dogs secrete saliva and digestive fluid in his presence as well,

rather than exclusively to the presence of food in response to which the dogs reflexively and automatically secrete saliva and digestive fluid (Spence 1978).

I. P. Pavlov and his associates systematically and methodologically administered for several times a neutral stimulus (i.e., sound of a bell) to the dogs just before they were presented to their usual food, that is, a meat powder. When this trial was conducted numerous times, I. P. Pavlov and his associates observed that the dogs were also secreting saliva and digestive fluid when the stimulus of the sound of the bell was administered alone, that is, in the absence of food (Shanks 1995). Ultimately, I. P. Pavlov came to the conclusion that the constant pairings of the sound of the bell and the food resulted in the formation of an association between the sound of the bell and the food. Specifically, the sound of the bell which at the beginning was neutral stimulus, a stimulus that does not elicit a response, acquired the capacity to elicit a response that is qualitatively similar to the one that the food naturally and automatically elicits. The dogs' response became classically conditioned and respectively the sound of the bell turned into a conditioned stimulus. Consequently, the new response that was learned as a reaction to the sound of the bell is termed a conditioned response (Schachtman 2011).

The Evolution of Classical Conditioning

The theory of classical conditioning has considerably evolved after the work of I. P. Pavlov in conditioned reflexes. The initial model of classical conditioning was operationally and theoretically elaborated by the work of several learning theorists in the USA. Specifically, theorists in the field of learning in the USA formed different techniques for assessing the functional qualities of associations between conditioned stimuli and unconditioned stimuli. In addition, they also found new conditioning processes and reinterpreted the fundamental processes of the conditioning that became known through the procedures that I. P. Pavlov proposed (Wills 2012).

A considerable factor that let to substantial modifications of the initial theory of classical conditioning is the integration of cognitive functions

in it. Specifically, even though the work of I. P. Pavlov on conditioned reflexes was widely spread in the USA, it received a considerable amount of criticism in 1950. Most of the criticism on his ideas was expressed in 1950 by the well-known Polish neurophysiologists named Jerzy Konorski and Stefan Miller. Jerzy Konorski and Stefan Miller initiated the primary cognitive conceptualization of respondent conditioning. Their work constitutes the precursor of the well-known and highly influential Rescorla–Wagner model of classical conditioning (McSweeney and Murphy 2014). In addition, at the same period, the psychiatrist Joseph Wolpe as well as the psychologists John Watson developed treatment plans that were based on the principles of classical conditioning so that to change dysfunctional behaviors into functional ones. This attempt to apply learning principles in the development of clinical interventions became known as behavioral modification and significantly increased the use of such interventions by psychiatrists and psychologists (Staddon 2014).

The theoretical conceptualization of classical conditioning has significantly changed with the introduction of the Rescorla–Wagner model in classical conditioning in 1972 (McSweeney and Murphy 2014). The Rescorla–Wagner model proposes that while living beings interact with their environment, develop causal expectations that enable them to estimate the relationships between environmental conditions. According to this model, learning involves acquiring knowledge related to the way that the environment is causally organized. Specifically, an organism becomes able to achieve learning by developing solid associations between environmental components (Rescorla 2008). Yet even if the environmental components become contiguous and in turn organisms form associations between them, the environmental components need to also allow the acquisition of knowledge related to causal relationships. In other words, the fundamental idea is the concept of contingency and how an organism perceives it (McSweeney and Murphy 2014). This model by integrating cognitive elements within the formation of associations indicated the acceptance of both cognitive functions

and associative processes in the brain, something that quickly earned the favor of experimental psychologists (Klein and Mowrer 1989).

Even though living beings sometimes form conditioned associations based only on a conditioned stimulus-unconditioned stimulus contiguity, there are numerous cases in which learning appears to enable living beings to anticipate the presentation of the unconditioned stimulus due to the presentation of the conditioned stimulus. In such cases, learning takes place through a contingency relationship that is probabilistically manifested (McSweeney and Murphy 2014). For instance, when the likelihood of the unconditioned stimulus being presented is equal with the likelihood of the conditioned stimulus being and not being presented, the conditioned association cannot be achieved. In contrast, when the likelihood of the unconditioned stimulus being accompanied by the conditioned stimulus is higher than the likelihood of the unconditioned stimulus being presented in the absence of the conditioned stimulus, a conditioned association could be achieved. For that reason, respondent conditioning is considered to reflect the ability of living beings to identify and learn possible associations between signals and important environmental conditions (Staddon 2014).

Nowadays, respondent conditioning is viewed as a multifaceted associative mechanism that involves many types of responses, rather than involving only glandular and visceral reactions, as it was initially considered. Respondent conditioning among other factors also relies on how relevant is the conditioned and the unconditioned stimulus, the appearance of other stimuli while conditioning takes place, and the degree of surprise that the unconditioned stimulus evokes (McSweeney and Murphy 2014). In addition, the evolution of the connectionist framework that models human cognition revived the attention in respondent conditioning as a productive technique for the study of associative learning. Therefore, nowadays, classical conditioning is most accurately defined and designated by its procedural method, which encompasses the preservation of firm control over the presentation of stimuli (Shanks 1995). In addition, it is highly

important to take into consideration that the principles that accurately differentiate classical conditioning between other forms of associative learning, such as operant conditioning and associative memory, are limited. Specifically, classical conditioning is most accurately differentiated by the extent to which the form of the conditioned response is determined by the choice of the unconditioned stimulus. Furthermore, a classically conditioned response is usually unaffected by instrumental contingencies. For example, pigeons cannot be easily prevented from pecking (conditioned response) at a separate key light (conditioned stimulus) which was paired with food (unconditioned stimulus) even if pecking stops the distribution of food (Wills 2012).

The Discrepancy Between Unconditioned and Conditioned Responses

I. P. Pavlov proposed through his work on conditioned reflexes that the same response that was elicited by an unconditioned stimulus could also be elicited by a conditioned stimulus through its association with the unconditioned stimulus (McSweeney and Murphy 2014). However, it quickly became clear that conditioned responses are of lower intensity than unconditioned responses. In addition, research related to classical conditioning after I. P. Pavlov's work has reliably proposed that the unconditioned response and the conditioned response are not the same responses, but they are usually qualitatively similar. Specifically, it has been cited that I. P. Pavlov's dogs did not confuse the sound of the bell with the meat powder, but they actually responded to the association among the sound of the bell and the meat powder which has consistently been presented right after the sound of the bell (Ramnero and Torneke 2011). In addition, the unconditioned response as well as the conditioned response is not limited to the secretion of saliva and digestive fluid. Specifically, the secretion of saliva and digestive fluid constitutes just a part of a multifaceted response through which the dog's body is being prepared for obtaining the meat powder (Staddon 2014).

Classical conditioning enables environmental components and/or conditions to acquire a

physiological capacity that did not have before. In other words, an environmental component and/or a condition that possessed other functions or none now acquires a new function, an acquisition that has adaptive significance for any species. Specifically, classical conditioning provides to a living being the chance to alter its behavior and thus increasing its capacity to adapt and survive (Ramnero and Torneke 2011). For example, a kid might jump on a road full of cars, lacking the association between such situations and threat. However, the kid possesses a physiological system that responds to specific unconditioned stimuli such as abrupt cries, screams, and violent acts with an unconditioned response of fear. In a plausible scenario where his/her mother or his/her father responds with a loud scream or exhibits a violent act when the kid tries to jump on the road, the road and/or other relevant stimuli would acquire qualitatively similar functions with the unconditioned stimulus of a loud scream, enabling the road and other relevant stimuli from then on (conditioned stimulus) to induce a conditioned response of fear. The acquisition of this new association would enable the kid to alter his/her behavior when it comes to a crowded road. A further example that depicts the way that classical conditioning could enhance the capacity for adaption and survival is a woman who is attacked on a remote parking place. One month later she goes to the same parking place and she begins to feel dizzy, chest pains, numbness in the hands, and a sense of terror and as a result she immediately leaves the place. In this scenario, the woman became classically conditioned to a previously neutral stimulus (remote parking) which has now induced a physiological response of fear due to its association with the unconditioned stimulus of assault, leading the woman to leave immediately from the remote parking and avoid a possible future attack (McSweeney and Murphy 2014).

The Relationship between Basic Affects and Conditioned and Unconditioned Responses

Human beings are endowed with a variety of responses and the environmental conditions in which they are induced rely on the individual's

learning history. A person's affective reactions of happiness, anger, or fear are governed by many factors. These affective reactions are not completely biologically endowed to humans, but they are formed to a high extent through the individuals' specific environmental experiences (Baum 2017). Meanwhile, it has been consistently cited that features of these affective reactions appear in people universally despite culture and ethnic variations. In addition, a significant amount of research proposes that people inherit either a small number of basic affects or a number of emotional mechanisms that are induced inevitably under specific conditions (Ramnero and Torneke 2011).

In 1870s, Charles Darwin proposed that human beings as well as other living beings are endowed with a set of basic affective responses that assist them to survive (Thines). Today, the research community did not reach a consensus when it comes to the exact amount of these basic affects and the responses that each one of them consistently induces, yet researchers agree that disgust, anger, sadness, fear, and joy constitute basic affects (Baum 2017). Each one of these basic affects is facially expressed in a specific way that is easy to be observed especially on the face. In addition, the basic affects could also be differentiated through the biological reactions they induce (Ramnero and Torneke 2011). Moreover, basic affects have the potential for certain types of behaviors and/or the predisposition for specific types of actions. For example, once an individual experiences the affect of fear her/his heart rate increases, specific muscles are stimulated, as well as blood flow is altered (Baum 2017). This sequence is considered to be an integral part of the basic affect of fear. For example, by the time an individual perceives that she/he is experiencing fear, her/his body had already activated biochemical reactions so that to prepare her/him for certain kind of actions such as fight or flight. In other words, the basic affective reaction of fear prepares humans for instant acts so that to be able to survive hazardous situations. Similarly, the basic affect of disgust prepares the body so that to move away from unwanted as well as dangerous smells and tastes such as poisonous food, and

anger entails bodily preparation for an attack. That is, by the time an individual perceives that she/he is experiencing anger, her/his body had already been prepared to attack (Thines 1987).

Affective Responses that Are Governed by Unconditioned Responses

Research related to classical conditioning has consistently suggested that affective responses are governed by unconditioned responses that have been shaped through evolutionary history so that to help humans to adapt and survive (Baum 2017). However, the research related to the mechanism and/or conditions (unconditioned stimulus) that induce such affective responses has not been yet fruitful. Specifically, the majority of research studies have included adults as participants, yet an adult person plausibly has a lengthy history of learning (McSweeney and Murphy 2014). However, it has been consistently cited that there are numerous stimuli that are not learned, yet induce a response of fear. Such stimulus includes sounds of high intensity, objects getting near fast, loud noises, and specific facial expressions of other individuals (Ramnero and Torneke 2011). Through the lens of an evolutionary perspective, it is not plausible to presume that there is just one kind of stimulus that is able to induce, for instance, fear or anger. That is, if these emotional responses ought to enhance adaption, and thus help an organism to survive, they must be triggered in numerous settings, yet the discrepancy between the stimulus would not have to be very high to have an influence early in a person's life (Baum 2017).

Classical Conditioning and Emotional Functioning

Classical conditioning could be used to gain an insight into the way that a person's emotive experience of the world is developed during childhood. For instance, despite the fact that only certain stimulus could induce fear responses early on in an individual's life, as the person grows up would acquire further associations which will obtain qualitatively similar operations with the ones that an unconditioned stimulus possesses, which would from then on induce fear responses

(McSweeney and Murphy 2014). Therefore, through classical conditioning, phenomena acquire new associations with external stimuli such as behaviors of other people, certain environmental conditions as well as internal stimuli, such as other emotions and interoceptive experiences. For example, a young boy who experiences sadness and is recurrently challenged by a father who is behaving in a manner which induces fear in the boy, via the process of classical conditioning, the father's behaviors could lead the young boy to develop an association between the affects of sadness and fear, and thus every time he feels sadness (conditioned stimulus), a response of fear is induced. In other words, this boy has learned through classical conditioning to experience fear every time he is sad (Thines 1987).

Classical conditioning shapes individuals' responses from early on in their lives and continues to influence the way in which a person relates to the world during the course of all of his/her life (Ramnero and Torneke 2011). The recognition that affective responses could also be induced by classically conditioned associations has its roots early in the development of behaviorism (Thines 1987). Specifically, John Watson, who is considered the father of "behaviorism," embraced I. P. Pavlov's work on conditioned reflexes and decided to implement its principles to investigate the way that the affective response of fear emerges in people. In addition, classically conditioned responses are fundamental to gain an insight in the way that individuals who experience trauma respond to a specific stimulus such as loud noises, fire, dark, or a preparator's perfume (Shanks 1995).

Stimuli of External and Internal Nature

Conventionally, behavioral psychotherapy has directed its attention on external stimuli, that is, stimuli that reflect alternations that occur outside the organism. However, the last few decades, researchers have also focused on internal stimulus (Klein and Mowrer 1989). Internal stimuli constitute alternations to the conditions within the body such as emotions, cognitions, hunger, thirst, and pain. Internal stimuli have the predisposition to also acquire conditioned associations, and the

term that is used to describe and designate such phenomena is called interoceptive conditioning (Schachtman 2011). Interoceptive conditioning is considered to be vital to the understanding and treatment of specific anxiety disorders such as panic disorder and phobias.

Biological Predisposition in Learning

Humans are endowed with a number of reactions to unconditioned stimulus, yet the responses that people exhibit are more complex than that. What is termed neutral stimulus, sometimes its function is not completely neutral (Ramnero and Torneke 2011). Specifically, stimuli could be differentiated in their ability to acquire conditioned associations and not all reactions could be induced by a previously neutral stimulus in the same time-framework and potency. For example, in order for a sound of a bell to acquire the capacity to induce an eyeblink to a human being, the sound of the bell and the puff of air have to be associated multiple times. Yet for instance, in order for a formerly neutral stimulus of a specific odor to induce a feeling of disgust and dizziness, a person has to experience once or maybe a few more times the association between the odor and a vomit (Spence 1978). Similarly, research related to affects proposes that it appears as if organisms inherited the capacity for specific types of leaning. For example, humans are more likely to exhibit fear towards a snake, height, and dark, rather than to a series of other stimuli. This is also true for conditions and circumstances in which people get scrutinized as well as abandoned by other people and in situations where people experience unfamiliar bodily sensations. Therefore, classical conditioning constitutes a mixture of genetically endowed elements and personal interaction with one's environment (Baum 2017).

Facilitating Factors

As already mentioned, conditioned associations constitute a response to the relationship between an unconditioned stimulus and another stimulus that was formerly neutral or unconnected to a certain setting. Accordingly, the nature of the exact relation between the associated stimuli is of ultimate significance (Schmajuk 2010). In

addition, there is a variety of factors that facilitate the acquisition of classically conditioned associations. Firstly, when the frequency with which a conditioned stimulus is presented together with an unconditioned stimulus is augmented, the likelihood that the conditioned stimulus would acquire the capacity to induce a conditioned response would be also augmented. For instance, if the frequency with which a sound of a bell accompanies the puff of air in a person's eye area is consistently augmented, the likelihood that the sound of the bell would induce a conditioned response of an eyeblink is augmented (McSweeney and Murphy 2014).

Secondly, when conditioned stimuli are constantly presented when the unconditioned stimuli are presented, the likelihood that a conditioned stimulus would induce a conditioned response would be higher compared to cases in which the unconditioned stimulus presents too in the absence of the conditioned stimulus (Schmajuk 2010). For instance, if the sound of the bell is permanently presented when the dog receives food, the likelihood that the sound of the bell would induce a classically conditioned response of saliva secretion would be augmented. In contrast, if the sound of the bell is presented only in specific times when the dog is receiving food, the likelihood that the sound of the bell would induce saliva secretion would be decreased. In addition, if a man engages in a consistent use of a specific cologne just in cases in which he engages in sexual intercourse with his wife, the likelihood that the aroma of this cologne would induce sexual arousal to the couple would be augmented (Ramnero and Torneke 2011).

In addition, classical conditioning necessitates a precise and a constant sequence of stimuli in which the unconditioned stimulus must follow the conditioned stimuli's presentation and not the other way around (Spence 1978). For example, in order for a tone to acquire the capacity of inducing an eyeblink, the tone must be presented just before or as the puff of air is received. If the tone is presented after an individual has received the puff of air around the eye area, this individual would never learn to classically respond with an eyeblink in the presence of the tone, despite the

number of times that this sequence of stimuli is repeated (Shanks 1995). A further factor that facilitates conditioning is the intervening time between the presentation of the conditioned stimuli and the unconditioned stimuli. Specifically, as the intervening time between the presentation of the conditioned stimuli and the unconditioned stimuli is increasing, the likelihood that the conditioned stimulus would induce a conditioned response is decreasing. For example, if a tone is presented a long time before an individual receives the puff of air, the tone would not acquire a classically conditioned association with the puff of air (McSweeney and Murphy 2014).

The definite relationship between the associated stimuli is not the only factor that governs conditioning. People possess potent biological tendencies that could alter this. For example, nausea could easily become conditionally associated with other stimuli (Baum 2017). That is, if an individual has a delightful plate of pasta and then a few hours later he gets a flu, the features of that plate of pasta such as its aromas and sense of taste could acquire classically conditioned associations with the sensations related to a flu and in turn induce a conditioned response of nausea regardless of the fact that a significant amount of time has passed between the presentation of the pasta's aromas and sense of taste, the flu (unconditioned stimulus and nausea (unconditioned response). That is, the pasta's aromas and sense of taste have become conditioned stimuli and acquired the capacity to induce nausea (Wills 2012).

Further Conditioning: Second-Order Conditioning, Generalization, and Discrimination

Second-Order Conditioning

Stimuli that have acquired conditioned associations can set the ground for further conditioned associations. For example, when a kid experiences fear in the presence of darkness resulting to the darkness being a conditioned stimulus that induce a response of fear, an additional stimulus that exists in the setting of darkness such as specific noises can acquire too qualitatively similar

operations with the conditioned stimulus and induce a fear response despite the fact that these noises did not accompany the stimulus that initially induced the fear response in the dark setting (Ramnero and Torneke 2011). This phenomenon is usually termed second-order conditioning. Once more, the stimulus of darkness is likewise one that is not so neutral, as humans are biologically predisposed to more easily associate it with fear than other stimuli (McSweeney and Murphy 2014).

Generalization

An additional and very significant functional process of classical conditioning is the propensity to react in a qualitatively comparable manner to similar stimuli, a process that is termed stimulus generalization (Staddon 2014). The term stimulus generalization when it comes to classical conditioning defines the process through which a specific response would spread in such a manner that other stimuli which have qualitatively similar traits with the initial classically conditioned stimulus would acquire the ability to also induce the classically conditioned response (McSweeney and Murphy 2014). For instance, a kid that has been scratched and wounded by a dog would not only respond with fear whenever sees that specific dog. Specifically, this kid is very well likely to respond with fear to the presence of dogs which are similar enough. However, if the kid was scratched by a large dog and the height of the dog is a dominant feature of the conditioned stimulus, it is likely that a very small dog would not induce a conditioned response of fear. Yet if the dog's barking is a dominant feature of the conditioned stimulus, then a very small dog's barking could operate as a conditioned stimulus and induce a conditioned response of fear. In other words, in order for an organism to respond in a qualitatively similar way to different stimuli, the stimuli must be similar enough (Ramnero and Torneke 2011).

Stimulus Discrimination

The opposite conditioning operation to generalization is a process termed stimulus discrimination. Stimulus discrimination is the capacity of

an organism to detect and respond to differences between stimuli, that is, the capacity to detect similarities among stimuli. For example, I. P. Pavlov's dogs at the beginning exhibited stimulus generalization since they were secreting saliva and digestive fluid in response to a variety of sounds that were different than the sound that was initially classically conditioned (Ramnero and Torneke 2011). However, if the dogs had consistently received only a specific sound before they were fed, their capacity to differentiate, that is, to discriminate, among similar stimulus would be enhanced and in turn, they would secrete saliva and digestive fluid only in response to the specific sound that precedes feeding (Shanks 1995).

The processes of generalization, discrimination, as well as the equilibrium among them are of vital importance for living beings in order to learn to adapt and survive (Baum 2017). Specifically, in some situations is of vital importance to exhibit stimulus discrimination and just respond to specific stimuli. For instance, a living being that must assess an area which is full of ice where a discrepancy in the white-color shows the degree to which is safe or dangerous to pass through the ice must have the capacity for stimulus discrimination. However, in other situations, stimulus generalization has higher adaptive and survival significance, such as the case of an organism which is chased by a variety of predators. In such a scenario, this living organism must respond to everything that presents in front of it.

Extinction

Classical conditioning and its derivative processes such as stimulus generalization and discrimination are dynamic in nature. Consequently, classically conditioned associations could be loosened and ultimately be extinguished, a process that is termed extinction (Ramnero and Torneke 2011). In classical conditioning, the term extinction indicates that the unconditioned stimulus does not any more accompany the conditioned stimulus, something which eventually leads to the termination of the conditioned response (McSweeney and Murphy 2014). For instance, in the experiment that I. P. Pavlov conducted, dogs were classically conditioned to secrete saliva and digestive fluid in

response to a sound of a bell. However, at some point in time, the sound of the bell was consistently occurred to the dogs in the absence of the food (unconditioned stimulus), leading to the extinction of the conditioned response of saliva and digestive fluid secretion. In other words, the sound of the bell did not any more operate as a conditioned stimulus due to no longer being followed by the unconditioned stimulus (food) which means that the sound of the bell lost its capacity to induce the conditioned response of saliva secretion (Shanks 1995). Yet as I. P. Pavlov indicated a classically conditioned response that became extinct is prone to reconditioning. Specifically, I. P. Pavlov got two of his dogs so that to test this assumption. The first dog was initially classically conditioned to secrete saliva, a response that then became extinct. The second dog had never learned the association between the sound of the bell and the food. Then he set the conditions so that both of them could learn the association between the sound of the bell and the food. The dog that once associated the bell with the food learned the association between the two stimuli significantly earlier than the other (Spence 1978).

Extinction is a multifaceted behavioral mechanism that has been recently found not to remove the initial learning experience (Ramnero and Torneke 2011). For instance, I. P. Pavlov indicated that a reaction that became extinct sometimes spontaneously reappears in the future, a phenomenon that is termed as spontaneous recovery. Subsequently, the phenomenon of spontaneous recovery has been experimentally verified in the field of both respondent and operant conditioning (McSweeney and Murphy 2014). However, the phenomenon of spontaneous recovery does not always appear and when it does appear is usually for a short period of time. In addition, when spontaneous recovery takes place the conditioned response is of lower intensity than it used to be (Schmajuk 2010).

Experimental Procedures

As mentioned above in respondent conditioning, an originally neutral stimulus acquires classically conditioned associations with biologically

relevant stimuli. In appetitive conditioning, the biologically relevant stimulus is positive for an organism such as food and originates behaviors of consummative nature in living beings. In contrast in aversive conditioning, the biologically relevant stimulus is negative in nature for an organism such as pain and initiates defensive responses like avoidance and escape (McSweeney and Murphy 2014).

Conventionally, research related to respondent conditioning has focused on excitatory conditioning (Shanks 1995). Excitatory conditioning occurs when a conditioned stimulus maintains a positive relationship with the unconditioned stimulus. That is, in excitatory conditioning, the conditioned stimulus acquires the capacity to predict the appearance of the unconditioned stimulus (Schachtman 2011). In contrast, in inhibitory conditioning, the conditioned stimulus acquires the capacity to predict that the unconditioned stimuli are not going to occur. Specifically, conditioned stimuli that acquire inhibitory qualities, when they present they indicate the nonappearance of either positive or negative unconditioned stimulus which in turn leads to the inhibition of the conditioned response by a living creature (Schmajuk 2010). This kind of conditioning was studied by I. P. Pavlov, and there has been a renewed interest for it the last few decades (McSweeney and Murphy 2014).

Conclusion

Due to the operational procedures of classical conditioning in which two stimuli are presented at the same time, it is considered that learning related to this associative connection relies on the dynamic characteristics of stimuli-stimuli associations. Additionally, research related to this hypothesis indicated that the conditioned stimulus acquires the capacity to trigger a representation of the unconditioned stimulus that has been associated with it (Shanks 1995). As mentioned above theorists and experimenters directed their focus on classical conditioning for various reasons. Firstly, classically conditioned associations acquire the capacity to fundamentally

influence organism's behavioral responses. Specifically, classically conditioned associations constitute a mechanism which enables organism to adapt to impending biologically important conditions (Schachtman 2011). Moreover, the operational principles of classical conditioning enabled mental health professionals to develop and implement effective treatment interventions for affective abnormalities and substance abuse. Last but not least, Pavlovian conditioning equipped learning theorists and researchers with an efficacious experimental design that enables for a significantly accurate analysis of the way that organisms form associations between environmental and interoceptive stimuli (McSweeney and Murphy 2014).

Definition

The various environmental conditions and forces that ultimately guided and shaped the evolution of humans.

Introduction

Environmental changes can be fatal to any biological life form. Each and every living organism is essentially a biological response to both its ancestral and present environmental pressures. Every facet of the environment and climate can influence an organism's nature, and many anthropologists claim that the human species is a result of an extensive and diverse environmental history. Evolutionary theory is founded upon an organism's ability to adapt to its environment, whether natural or artificial. Evolutionary psychology assesses both prehistoric and present environmental conditions, which contribute to the development of the field's hypotheses and theories.

General Climates and Habitats of Human Evolution

Prehistoric humans, also called *hominids*, evolved in Africa. Today, modern humans dominate every continent and reside within one of almost 200 different countries over the globe. Over millennia, various species of humans travelled across the world and encountered a wide variety of environments similar to those existing today, which include deserts, forests, woodlands, mountains, coasts, islands, and Arctic regions. Early humans have a long history of hunting and gathering, which demanded them to explore beyond their "homes" or "campsites" in order to collect necessary natural resources for survival. With drought and famine usually within weeks away, prehistoric humans had every right to abandon their original habitats (Harari 2015).

Hominid diasporas were a powerful force that drove human evolution. The fluctuating temperatures, sea levels, and animal and vegetable life made survival the most onerous task (National Research Council 2010). To an extent, scientists

are able to unveil prehistoric climatic and environmental conditions with measurements of oxygen isotopes (Elton 2008; Potts 2016). Following the ice age, tropical climates and vast expansions of vegetation intercepted hominids' journey across the globe (National Research Council 2010), which diversified all forms of life. Typical foods gathered and eaten by modern humans, or *Homo sapiens*, included berries; onions; mushrooms; roots; seeds; bugs; smaller animals, such as rabbits, fish, and turtles; and occasionally large predatory animals like bison and mammoths (Harari 2015), which all do not share a sole natural habitat.

Natural disasters – volcanic eruptions, hurricanes, floods, etc. – and other demographic pressures compelled *Homo sapiens* to settle for different and novel habitats. An organism's *environment* is not restricted to its physical surroundings; other organisms also serve as a selective force of nature. There were periods where *Homo sapiens* were not the only human species living on Earth; *Homo neanderthalensis*, often referred as the *Neanderthal*, once shared present-day Europe with *Homo sapiens*. Neanderthal deoxyribonucleic acid (DNA) is found in modern Middle Eastern and European humans. Some anthropologists and biologists claim that, on rare occasions, *Homo sapiens* and the Neanderthals were capable of producing fertile offspring (Harari 2015). Nonetheless, the time Neanderthals and *Homo sapiens* shared together was relatively short-lived. *Homo sapiens* settled in uninhabited habitats, like Australia, that was home to animals that did not evolve to fear humans, which led to the extinction of countless species. Neanderthals went extinct shortly after the arrival of *Homo sapiens*, giving *Homo sapiens* the reputations of being both the most adaptable species yet (Potts 2016) and the most widespread "ecological serial killers" (Harari 2015).

Effects of Environmental Diversity on Human Evolution

The biological evolution of humans merely coincides with major environmental and climatic change (Potts 2016). *Homo ergaster*, for example,

is believed to have a body that was highly adaptable to heat (Potts 1998). Hominids that adapted to colder climates often had shorter appendages and a wider torso, similar to the Neanderthals (Elton 2008). Although physical attributes acquired from environmental pressures may seem evident, adapting to novel environments requires a more versatile lifestyle. Organisms, including hominids, that do not adapt to climate and environment change are more likely to be exterminated than those with at least some ability to adapt habitual change. The desiccation of arboreal habitats produced thousands of square miles of open and flat land in Africa. Bipedalism, walking on two legs, is hypothesized to have evolved from this environmental change, which is also known as the *Savannah hypothesis* (Potts 1998; Elton 2008).

Physical attributes were not only acquired from the natural forces hominids endured. The ability to adapt to a novel environment requires new intelligences and skills, such as making tools and shelter, controlling fire, and establishing social order (National Research Council 2010; Harari 2015). Scholars argue that *Homo sapiens* inadvertently evolved to become dependent on tools and technology. The human diet, for example, would be drastically limited if there were not any means to cook food. Prolonged physical and mental maturation may also be results of humans' rich environmental history. Some scientists even hold environmental and climatic diversity responsible for the enlargement of the human brain, complex symbolic expression, and social structures similar to modern societies (Potts 2016).

Millennia ago, hunter-gatherers had to scrutinize their environment in order to discern cues that could predict seasonal and weather changes (Harari 2015). Today, human beings will somberly call a desert, mountain, forest, island, or Arctic region their permanent home unless under the constant threat of natural disasters (Elton 2008). Perhaps the most precious feature from human's evolutionary history is cultural diversity. The natural lifestyle of a band of humans was rarely identical to another that lived elsewhere (Potts 2016). Humans may have paid an irrevocable price while spreading across the world, but

they may also have acquired the finest survival skills and instincts Earth has ever witnessed.

Variation Selection and Habitat-Specific Hypotheses on Evolutionary Psychology

Like all other species, *Homo sapiens* have a fixed set of environments that they can survive and reproduce in, yet environmental instability is the best impetus for adaptation development. While some scientists consider *Homo sapiens* as a biological product of various and diverse environments, others consider them as a biological product of specific ones, the former being the *variation selection hypothesis* and the latter as the *habitat-specific hypothesis*.

The relatively large biological reaction norm, or phenotypic plasticity, is ultimately what permits human cultural and biological diversity. Body shape, stature, and skin, among other traits, vary between individuals with ancestors from different regions of the world. Human cultural and biological diversity supports the variation selection hypothesis; however, there are reported universal preferences for geographical landscapes and climates that resemble the African Savannah, which embody the popular *Savannah theory*, a habitat-specific hypothesis (Potts 2016).

Regardless of the two competing theories, the environments in which humans acquired their adaptations or their *environment of evolutionary adaptedness* (EEA) are at the forefront for the development of evolutionary psychological hypotheses. Given that adaptations resulting from natural selection can be both physical and mental, a sense of adaptive universality among humans across all cultures is fundamental in evolutionary psychology. Ruling out alternative explanations for universal psychological traits and tendencies is a current objective of empirical research within evolutionary psychology.

In spite of the endeavor to synthesize human paleoanthropology and psychology, most social and behavioral scientists advocate for theories that are independent of biological evolution. The *blank slate* theory posits that human behavior is solely a product of knowledge, will, and experience (Pinker 2016). Many social scientists often

view *nature* and *nurture* as conflicting explanations for human behavior, but accumulating evidence within evolutionary psychology may reconcile the two. After all, an environment-rich evolutionary history is likely to yield species with seemingly perfect and malleable minds.

Conclusion

The evolution of hominids encompasses a wide array of environmental pressures that make it difficult for anthropologists to summarize concisely. The famous hominid diasporas out of Africa presented hominids with novel habitats and ecosystems that served as catalysts for human evolution. Although only fossils and artifacts are what remain from human prehistory, measurements of oxygen isotopes, among other scientific and forensic procedures, allow scientists to estimate prehistoric climates and environments. Assessments of the diverse environmental conditions that existed during human evolution serve as the foundation for evolutionary psychological research. Every adaptation, whether physical or mental, is a response to a range of environmental pressures. The psychology and behaviors of *Homo sapiens*, indeed, exhibit the blank slate's assertions, but *Homo sapiens* also have a reputation for terraforming habitat after habitat, which necessitates a versatile mental capacity.

Climate and Use of Spices

Angelina Jong

University of Bristol, Bristol, UK

Synonyms

[Spicy food in hotter countries](#)

Definition

Foods eaten with more spices are found more often in hot climates. Some suggest that the use of spices by humans may be an evolutionary adaptation to fight against food poisoning.

Introduction

Spices are “dried, fragrant, aromatic or pungent plant substances . . . that contribute flavor, whose primary function in food is seasoning rather than nutrition, and that may contribute relish or piquancy to food or beverages” (Farrell 1998, p. 17). Spices include pepper, onions, garlic, parsley, and so on. Although spices are now easily obtainable all over the world, there is a common tendency to relate spices to some cuisines more than others. A few notable examples are the “spicy” foods of India, Mexico, and Indonesia,

whereas Swedish, British, and Russian foods are not known to be particularly “spicy.” Even a cursory glance reveals an interesting pattern: there would appear to be some correlation between spiciness of the cuisine and the climate of its country. Indeed, there has been much discussion about why it seems that people who live in warmer climates use more spices in their cooking compared to those in colder climates.

One theory, by Billing and Sherman (1998), suggests that humans’ use of spices has evolutionary roots and that the link between climate and the use of spices could be explained by the spices’ antimicrobial properties.

The Antimicrobial Theory

The acquisition and consumption of food, although necessary, pose risks. Microorganisms and toxins that inhabit food can cause people to fall ill and may even result in death. This was an especially severe problem in the days before refrigeration and artificial preservatives were in wide use. The use of spices in food has been suggested as an adaptive solution to this problem. Spices, which are derived from plants, possess secondary compounds which act as the plants’ defense mechanism against harmful organisms.

In order to test the theory that spices have been used for their antimicrobial properties, Sherman and Billing (1998) studied 4578 traditional meat-based recipes from 36 different countries. Recipes from traditional cookbooks were used as considered by Billing and Sherman (1998) as artifacts of human behavior. Meat-based recipes were used because unrefrigerated meat spoils quicker than unrefrigerated vegetables, and there were more meat-based recipes available in traditional cookbooks. The use of 42 spices in these recipes was catalogued along with each country’s mean annual temperature. They set up several key predictions of their antimicrobial theory.

1. Spices used in cooking should inhibit food-spoiling microorganism activities.

If spices do inhibit the growth of harmful food-borne microorganisms, using spices would aid in the reduction of food poisoning. Of the spices located by Billing and Sherman (1998), half inhibited the growth of more than 75% of bacteria. Laboratory tests of the efficacy of spices against microorganisms have used concentrations of below 1000 parts per million or ppm, while the recipes in Billing and Sherman’s study roughly contained 250–1000 ppm of spices (e.g., Kivanc et al. 1991; Billing and Sherman 1998). This suggests that the concentration of spices used in everyday cooking is sufficient to inhibit microbial activity in food.

2. Use of spices should be greatest in hotter climates.

The rate of bacterial growth on meat increases drastically in a matter of mere hours if left unrefrigerated. This growth is further accelerated in hotter climates. Thus, if the antimicrobial theory holds true, there should be a positive relationship between the use of spices (in order to fight food spoilage) and hotter climates. The data was found to be consistent with the prediction: the number of recipes containing spices and the number of spices in a recipe both increase in positive correlation with the mean annual temperature.

3. Use of spices with the most potent antimicrobial properties should be greatest in hotter climates.

Country-specific uses of highly inhibitory spices such as onion, garlic, and oregano, which reduce bacterial growth by 100%, were found to correlate positively with countries’ mean annual temperature. This pattern also holds true for other highly inhibitory (i.e., inhibiting more than 75% of bacterial species) spices. Although the use of dill and parsley was found to be negatively correlated with temperature, neither has a significant inhibitory effect. Billing and Sherman (1998) also note that two of the most frequently used spices, pepper and lemon juice, do not positively correlate with mean annual temperature nor are they powerful

bacterial inhibitors. Instead, they suggest that pepper and lemon juice work in conjunction with other spices in order to increase the antimicrobial effects of other spices.

4. Within a country, recipes from areas of lower latitude (i.e., warmer climates) should have a higher number of and more potent spices than recipes from areas of higher latitude (i.e., colder climates).

Although information relating to recipes based on regional latitudes was scarce, they were able to collect data from China and the United States. Data from both countries are consistent with the prediction and show patterns that are similar but less dramatic than those between countries: southern regions of the United States and China use spices more frequently and more potent spices in their recipes compared to those in southern regions.

Sherman and Hash (2001) further predicted that, within the same country, vegetable-based recipes should have less spices compared to meat-based recipes because vegetable-based food are associated less with food-borne illnesses than meats. When plants die, their cell walls are harder to break down for many microorganisms unlike in meat. In contrast, the main inhibitor of microorganisms in animals is the immune system, a system which completely ceases to function upon the death of the animal. To test this, they carried out a similar study with vegetable-based recipes. Throughout the 36 countries in the study, traditional vegetable-based recipes used significantly fewer spices compared to meat-based recipes. From the 41 spices that were compared, 30 were used significantly less often in vegetable dishes compared to meat dishes. There were also fewer vegetable-based recipes that used more than one spice or extremely potent spice. As the recipes and spices compared were within the same countries, the accessibility of spices in the different countries cannot explain the difference in spice use in different climates – the spices used in the recipes were actively chosen by people rather than dictated by what spices were available.

In further support of the antimicrobial theory regarding climate and the use of spices, Ohtsubo (2009) found that the predictions made by Sherman and colleagues also hold true using Japanese spices. He additionally predicted that more spices would be used in recipes that contained unheated main ingredients than recipes with well-heated ingredients. This is because unheated ingredients are more susceptible to food-borne pathogens. Datasets provided by experts in traditional Japanese foods supported the predictions of the antimicrobial theory.

Cost of Spices

As spices aid in preventing food spoilage, one might expect that although spice usage would be more useful in warmer climates, it would also be beneficial in colder climates. Therefore, the infrequency of the use of potent spices in recipes found in colder climates – even though most spices are available there – suggests that spice consumption may have its drawbacks (Billing and Sherman 1998). Plant secondary compounds in spices inhibit microbial growth but they can also have mutagenic, carcinogenic, and other ill effects when consumed (Beier 2000). Therefore, while the benefits of spices' antimicrobial effects outweigh the risk in warmer climates, this does not seem to be the case in colder ones. The slower rate of food spoilage, the possible health risks of spice consumption, and the higher price of obtaining spices probably explain why countries with lower mean annual temperatures use far fewer and less potent spices than warmer countries.

How Did It Start?

Although using spices to enhance the flavor of food is often the go-to answer as to why we use spices, this explanation is insufficient to explain how humans began to use spices. This can be seen in children who react negatively when.

Sherman and Billing (1999) suggest that spice use may have begun with spices that were

tasty or caused desirable aftereffects. Individuals and families who spiced their food may, then, be less likely to fall ill due to food-borne illnesses compared to those who did not use spices, especially in warmer climates. This information would have been passed onto their offspring and may have been imitated by other families observing the habits of the healthier family.

However, these individuals may still have become ill due to microorganisms growing resistance or exposure to new food-borne bacteria. Humans tend to develop food aversions to the taste of foods that have once made them ill (Milgram et al. 1977). Adding different spices that could kill the microorganisms and also change the taste of the avoided food would perhaps allow the once avoided food to be consumable again. Eventually, humans would prefer the taste of spiced food compared to unspiced food, especially in hotter climates where the growth of food-borne microorganisms is faster. This may be reflected in the large number of spicy recipes found in warmer climates.

Modern Day Examples

Spices do not only seem to aid in protecting our ancestors from food-borne illnesses. Although Japan and Korea are geographically proximate with similar mean annual temperatures and climates, bacterial food poisoning affected only 3 per 100,000 Koreans, while it affected 29.2 per 100,000 Japanese (Lee et al. 1996). The difference in the prevalence of food poisoning between the two countries can be attributed to the fact that Korean recipes contained more spices and more potent spices than that of the more delicate Japanese recipes (Billing and Sherman 1998). The Japanese recipes' lesser use of spices may stem from the abundant availability of fresh seafood in Japanese history. However, due to an increase in population and overfishing, there is an increase in the delay between catching and consuming the seafood, allowing the growth of harmful microorganisms on the food.

Alternative Theories

Although the antimicrobial theory provides a good explanation for why hotter climates are associated with the use of more spices, other alternative explanations have been put forward. Some include:

- Spices help disguise the smell and taste of food that may have started to spoil (Barker 1982).

This theory, although consistent with the trend that more spices would be used in hotter climates as there would be more bad smells to cover, overlooks the evolutionary disadvantage of masking food that may be ridden with food-borne illnesses. Covering up foul smells and tastes would cause humans to be more likely to consume spoiled food.

- Spices increase perspiration and cool down the body (Bosland 1994).

This cooling pattern only seems to hold true for only some of the spices used like chilies. Hotter climates are linked with the use of many other spices that do not increase perspiration. Furthermore, cooling of the body via perspiration is metabolically expensive and would not be a sustainable cooling strategy.

- There are no benefits to eating spices and that people consume whatever spices they have locally.

This is unlikely because, as mentioned earlier, availability of spices cannot account for spice usage patterns. Additionally, many spices are not immediately pleasant to consume especially in children. Children consume spices usually after being encouraged by their parents, suggesting that there is a benefit to eating spices that outweighs the initial displeasure due to their taste.

Conclusion

In sum, the frequency of spice use, the amount of potent spices, and the proportion of recipes that contain spices increase as the mean annual temperature of a country increases. This has been suggested to be due to the antimicrobial properties of spices. By consuming spices, humans were able to reduce the likelihood of contracting food-borne illnesses. However, there are also risks associated with spice consumption. Thus, recipes from different climates and different eras represent “records of our coevolutionary races against food-borne diseases” (Sherman and Billing 1999). Practices that promoted the health of spice users may have spread as a cultural meme and were more beneficial for those in hotter climates and those in colder climates.

Climate Fluctuations in the Last 200 Ky

Kian Betancourt
Hofstra University, Hempstead, NY, USA

Synonyms

[Catastrophes](#); [Climate change](#); [Global warming](#)

Definition

A change in global or regional climate patterns.

Introduction

Climate fluctuations are changes in the earth’s atmosphere due to an array of events that can temporarily or permanently change elements in the global or regional area. These changes can vary considerably, and climate fluctuations can be due to many potential causes. These changes can be from natural events such as earthquakes or volcanic eruptions, or more modern climate change can be seen as a result of human behavior and changes to the environment such as carbon emissions. However, in

order to understand what climate fluctuations are, it is very important to first discern two concepts that are often a point of confusion when talking about these changes – *temperature* and *climate*.

Temperature

Essentially, all that differentiates climate and temperature is a measure of time, and how long these effects go on for. Temperature is essentially a measure of atmospheric fluctuations in the short term that result in effects that we feel as humans in our daily lives. These are things that are much more noticeable to us, in general, rather than long-term climate fluctuations. Temperature is experienced every day simply by leaving one's home, and sometimes is even apparent by looking outside the window. In general, humans experience sensations such as hot weather, cold weather, rainy weather, humid and dry weather, heavy or light winds, snow, thunder and lightning, and so on. These are examples of short-term atmospheric changes that can have a profound effect on daily lives but can change quickly in a short period. For instance, there may be weeks whereby a stretch of some great weather comes that may be warm and dry, but soon followed by periods of heavy rain, winds, and humidity. These are all examples of weather fluctuations because of their short-term occurrence. Living in the northeast, for example, one might expect that in the months of December, January, and February to experience cold weather with snow as compared to months of June, July, and August whereby hot weather is typical. However, while unusual, it is not impossible to experience a very warm day in winter months, or a chilly day in summer months. These random fluctuations happen constantly and are a result of changes in our atmosphere. These are significantly different from something such as climate change, which can be exemplified by weather phenomena but are usually an accumulation or take place over a longer period of time.

Climate

While weather is usually defined as being the atmospheric changes within a short period of time (usually anything from within a few days to a few months, such as seasonal changes), climate is long term, typically over the course of years or decades. More specifically, it is usually indicative of *average* weather patterns over a period of time. For instance, back to the example of the northeast United States. Across anywhere north of the equator, one would expect that in the summer months (June, July, and August) warm weather would be typical as compared to the cooler months (December, January, and February). This is true across nearly every single region north of the equator, and south of the equator would be the opposite. However, the actual difference in this weather phenomenon is what is indicative of climate. Instead of “Is it cold?” or “Is it hot?” more importantly is the larger picture – more specifically, “How *much* colder?” or “How *much* hotter?” To once more refer to the northeast United States, one would expect that the difference between the coldest day in winter and the hottest day in summer would be pretty drastic, as compared to a place like the southeast United States, which in general typically has a warmer climate. As such, their difference between coldest and warmest day would likely be less drastic than that of the northeast United States. This difference is an example of climate – long-term temperature fluctuations or patterns that are often common to a specific area. The northeast United States, in general, experiences colder weather and more snow than do parts of the lower United States and other countries, especially as one gets closer to the equator. Therefore, the northeast United States has a colder climate than the southeast United States. There may be a day in a given year where Florida has a colder day on the same day than New York – this would be an example of a temperature fluctuation rather than a climate one, given that it is over the period of a day rather than decades. However, in the event that for 50 years, Florida has a successively warmer winter each year, then this is a result of climate change. The understanding of this difference is

essential in understanding why climate change and fluctuation was such an important part of our evolutionary past.

How Did Climate Fluctuations Impact Human Evolution?

Now that the differences between climate and weather fluctuations have been studied and understood, theories emerged that attempt to explain how major climate fluctuations began to impact early hominins, and how their being forced to adapt eventually paved the way for evolutionary changes we still see today. A major way to assess climate change is through the usage of oxygen isotopes. By looking at microscopic skeletons of certain creatures on the sea floors, it is possible to detect their oxygen isotopes that give a measure of how temperature has changed over time as well as rate of glacier melting, which also can show us forms of climate change. By looking at these oxygen isotopes, research has shown that there have been various climate changes as far back as we can detect (Behrensmeyer 2006). If this is the case, then we can determine that our ancestors such as early hominins were likely heavily impacted by these climate changes, and as a result likely had to make dramatic behavioral changes to accommodate to the changes in their environment around them to survive (Demenocal 2004). Modern research also shows that these climate fluctuations have become more dramatic the more hominins were evolving, suggesting that the most modern *Homo sapiens*, especially within the last few hundred years, have been a major contributor to the lasting and dramatic climate change that we see today (Potts 1996).

How Does Climate Change Affect the Environment?

All organisms experience the effects of weather-related fluctuations. For instance, looking outside a window and seeing that it is raining would typically invoke reaching for an umbrella. While an umbrella is obviously a more modern, human-

made creation, the point still stands that humans make small changes in daily behavior to account for the weather fluctuations that occur around us. All organisms do the same thing, especially with regard to seasons (for instance, certain animals changing fur colors to go along with a change in season). The difference between weather and climate fluctuations, however, is that the organism will continuously make these changes according to the weather. For instance, that same organism that changes fur color would only do so with regard to the weather phenomenon that it is experiencing. If there is no reason for a thicker fur, then it will not grow one as that would be maladaptive (a thicker fur would prevent cooling in warmer months, and so would be evolutionarily disadvantageous). It is only with climate change that we would begin to see permanent changes in an organism's behavior (Vrba 1995). For instance, if over the course of millions of years that fur-changing organism only experienced winter, it would eventually adapt to keep its winter coat on and avoid changing furs as there is simply no reason to. To use the umbrella example, if the climate changed such that it now rained every single day out of the year, humans would likely keep our umbrellas around constantly given that it is now reflective of the environment around us. This is an example of how climate change can drastically impact the behavior humans exhibit on a daily basis, and more specifically how our ancestors had to change their behavior in response to the climate change around them. When our behavior changes, and we have to adopt new behaviors to survive, evolution takes place over millions of years, whereby our physiological bodies will begin to adapt to whatever is necessary in our new environment to ensure survival (Ruff 1991).

What Kinds of Climate Change Did Early Hominins Experience?

Evidence shows that there were large-scale shifts in temperature and precipitation around 200,000 years ago that have only gotten progressively more variant over time (Stewart and

Stringer 2012). These changes can result in huge changes in their respective environments, affecting things such as vegetation and daily temperature. Living in trees may not have been suitable given these climate changes, especially if vegetation that was an essential part of our diet was no longer available. Our ancestors were then confronted with either dying because of the lack of resources, or changing their behavior to accommodate to their newly changed surroundings. As a result, the ancestors that did survive likely had to migrate closer to the forest floor, and begin looking for new vegetation that was not as heavily impacted by the climate change as were the things at higher elevations in the trees. In addition, different wildlife that represented prey would have been extremely valuable, ensuring survival. Therefore, the ancestors that failed to adjust would have died off, and those that did survive would continue to reproduce and raise children in the same environment, and they would emulate the same behavior. Over the course of long periods of time, this would become instinctive to early hominins and they would all begin to adjust to living life on the forest floor. From there, it is possible that the forest floor simply lacked sufficient resources or was too dangerous for these hominins, so they ventured out gradually until they found grasslands, which was eventually where they settled and developed more human-like qualities seen today. These qualities included things such as completely opposable thumbs, standing upright with a straight spine, usage of arms to do things such as throwing and creating weapons, bipedal locomotion, human speech and communication, and so forth (Trauth et al. 2007).

Other climate changes that may have drastically impacted the environment could have been things such as earthquakes or changes in tectonic activity. Earthquakes and shifting plates can completely change locations of lakes, rivers, mountains, valleys, and so on – also changing their respective environments and vegetation. When these changes occur, organisms face the dilemma of either dying or changing their behavior to survive, resulting long-term in evolutionary changes to adapt to their new surroundings (Füssel and Klein 2006). Other things include

volcanic eruptions and forest fires, which can change entire environments and even quality of breathing in certain areas, also drastically changing the way the organism can survive in that respective area.

Conclusion

The bottom line is that early hominins grew up in a time where environmental instability was very much prevalent (though not as prevalent as it is today). As a result, changes in the environment were very likely, such as changes in temperature, rainfall, tectonic plate shifts, earthquakes, forest fires, volcanos, and so forth. These events can cause changes in local environments, causing shortages of food, shelter, water, and other resources. When organisms such as early hominins are confronted with this change, they are forced to either relocate and find an environment that is more hospitable or be forced to survive in an environment that is inhospitable, and eventually evolutionarily change to adapt to their new environments. Alternatively, the organisms that cannot survive die off or fail to reproduce, resulting in endangerment and extinction of the species. The reason humans exist today is because these early hominins were able to adapt to their environment and move onto grasslands and out of trees to adapt to the climate fluctuations and changes to their environment, and thus resulted the physiological and biological changes seen in the human body to this day.

Climbing tools

Definition

Tools (*sensu* Shumaker et al. 2011) used as aids in ascending or moving the body up to or across

elevated substrates or objects. It includes vertical and angled climbing and clambering.

Introduction

The use of objects to assist in climbing was one of the first types of tool use reported in primates. A hundred years ago it was described in captivity for orangutans by R. M. Yerkes, and soon after for chimpanzees by W. Kohler, gorillas by R. M. Yerkes, and capuchin monkeys by J. A. Bierens de Haan (reviewed in Shumaker et al. 2011). Since then, the use of tools to aid climbing has been extensively observed in captive settings for these and other primate species. Comparatively, fewer observations of tools used as climbing aids have been reported for primates in the wild.

Evidence from the Wild

Chimpanzees

When infant chimpanzees become separated from their mothers by a large gap between trees, the mother pulls the branch where her infant is and holds it still until the infant crosses (Goodall 1986).

To access trees that they cannot climb directly, chimpanzees have been seen to use different types of tools. They prepared long sticks (including hooklike types) and, standing on a branch of a neighboring tree, used them to pull down one of the branches from the target tree, gripped it, and climbed into the target tree after several attempts (Sugiyama and Koman 1979). To access the same target tree, a chimpanzee detached several branches from a main branch of a nearby tree making it lighter; he then swung on it vigorously until he was able to grab a branch of the target tree and climb into it (Sugiyama and Koman 1979). To avoid the thorny branches when climbing in kapok trees (*Ceiba pentandra*), chimpanzees have been seen to place small branches under their feet (stepping sticks) or hands (“gloves”) (Alp 1997).

Once a wild chimpanzee used a human ladder abandoned on a tree to climb it (McGrew 2004),

but it was not described if the ladder was repositioned by the chimpanzee.

Bonobos

Bonobos use small trees as vehicles (bridges) to travel from one large tree to another, bending the small tree in a particular direction with their own body weight (Ingmason 1996).

Orangutans

Orangutans use flexible trees as vehicles to access target trees by swaying the vehicle tree in a specific direction until they get close enough to reach the target tree and climb into it. They remove lianas entangled on a vehicle tree by biting or pulling with their hands to release the tree and then sway it to reach a target tree (van Schaik et al. 2006). While swaying a vehicle tree, orangutans use long, hooklike sticks to bring a branch from the target tree closer, grab it, and climb into the tree (van Schaik et al. 2006). Orangutans use several leaves together as a cushion, transferring the tool several times between the hand and foot to aid in climbing the thorny branches of trees (van Schaik et al. 2006).

Gorillas

On one occasion, after trying to climb a bamboo thicket unsuccessfully, an infant mountain gorilla grabbed a pole the mother was holding vertically; then she turned toward the infant and seemed to intentionally hold the pole firmly while the infant used it to climb up to her (Grueter et al. 2013).

Western Red Colobus Monkeys

A female relocated and positioned an attached branch to aid her infant in crossing a canopy gap and climbing into the tree where she was (Shumaker et al. 2011).

Evidence from Captivity

Chimpanzees, orangutans, gorillas, bonobos, and capuchin monkeys have been reported to use four categories of tools as climbing aids for problem-solving in experiments, sometimes spontaneously

(reviewed in Shumaker et al. 2011). These categories are (1) balancing a vertical pole or other objects, (2) repositioning an object, (3) stacking objects in a tower-like construction, and (4) stabilizing and leaning an object against a vertical or inclined surface or other objects to use as a ladder. However, only chimpanzees have been observed to use a fifth category: employing sticks as “pitons” (McGrew et al. 1975). These climbing tool categories have been used by all five species to achieve the following goals: (1) to reach food or another desirable object suspended above the ground, (2) to access natural vegetation for exploration or ingestion, (3) to look through windows, or (4) to access elevated areas for exploration. Also, chimpanzees, orangutans, and gorillas have used climbing tools to escape from enclosures.

One group of chimpanzees spontaneously invented a surprising series of different climbing tools (Menzel 1973; McGrew et al. 1975). First, they made ladders by leaning sticks and poles firmly against walls, fences, and trees and then by setting up and stabilizing poles on top of the narrow edge of elevated structures. The goal was to access a window or to avoid electric wires before climbing into trees. Later, the chimpanzees used longer poles as ladders to escape their enclosure over a fence. At this point, caretakers removed objects that could be used as ladders from their enclosure. However, the chimpanzees detached parts of fallen trees, knocked down still-rooted tree stumps, up-rooted posts, from a former runaway system, detached planks by separating nailed joints, all to be used as ladders and escape their enclosure. They eventually broke apart planks attached by powerful iron screws and used them as ladders. Finally, when all objects large enough to be used as ladders were removed from their enclosure, the chimpanzees used straight, carefully selected sticks as pitons. They inserted them into seams or joints in the fence and climbed on them to escape tools stopped the escapades.

Orangutans have made “gloves” to avoid electric shocks by holding bunches of straw when climbing over an electric fence (Shumaker et al. 2011).

Macaques and baboons have also been reported to use tools as climbing aids (reviewed in Shumaker et al. 2011). Lion-tailed, Japanese, and Tonkean macaques spontaneously erected poles against vertical constructions to use as ladders, and chacma baboons were observed to balance sticks and shift a box to obtain overhanging food.

Conclusion

The use of tools to assist climbing by primates has a long history in captivity, but has been reported only rarely in the wild. Primates use climbing tools in the wild when (1) offspring need help to manage large canopy gaps or (2) climbing cannot be done directly because a tree trunk is too large for vertical climbing or has long spines or sharp edges that make climbing difficult. Wild chimpanzees and orangutans have invented similar tools to protect their hands and feet while climbing thorny trees and to reach target trees. But one of the most common types of climbing tools used in captivity, the ladder, has only once been reported to be used in the wild. Presumably, primates would benefit from using ladders to access trees full of fruits, flowers, or seeds that they cannot climb directly, (e.g. baobab, *Adansonia digitata*) but the importance of such difficult-to-climb tree sources has not been assessed in primate habitats.

The conditions that elicit the use of climbing assists may be more common in captive settings. Experiments in captivity facilitate the use of climbing tools to obtain rewards, access elevated targets, or escape. Most primate enclosures, even naturalistic ones, lack the complex three-dimensional world of wild primates, and boredom and curiosity may favor the invention of climbing tools in captivity.

Clothing

Ian Gilligan
Department of Archaeology, University of
Sydney, Sydney, NSW, Australia

Synonyms

Clothing refers to items worn to cover the body; terms such as [apparel](#) are synonymous. Clothing however must be distinguished from terms such as dress, costume, adornment and fashion which embrace a wider range of items and activities such as body painting and cosmetics.

Definition

The origin of clothing reflects the loss of hair cover in hominin evolution and the resulting vulnerability of humans to cold stress during the global climate changes of the ice ages. Alternative theories about the origin of clothes suggest a universal human inclination to cover the naked body for reasons of decorative display or modesty, yet these motives are not corroborated by ethnographic data from recent naked hunter-gatherers. Despite an absence of actual clothing remains due to perishability, a thermal origin is supported also by archaeological evidence which links the development of clothing-related technologies in prehistory to past glacial cycles and environmental conditions. Thermal physiology was similarly responsible for the advent of textile garments after the last ice age in the context of global warming, as woven fabrics provided enhanced permeability to perspiration in the warmer and more humid conditions. Demand for textile fibers

was a key aspect of the agricultural revolution, encouraging the domestication of plants and animals. While biological factors were paramount with the origin of clothing, psychosocial factors such as modesty and the rise of fashion as the basis of habitual cover had a profound influence on social evolution and the emergence of modern civilized life.

Introduction

Clothes are what most visibly set humans apart from all other species. In fact no other technology plays such an intimate part in the everyday lives of modern humans. Yet of all our major inventions, the least is known about the origin of clothes. One reason is that clothes do not survive for long in the archaeological record. Another factor contributing to an academic neglect is a gender bias: Clothes are generally considered more a feminine concern.

Clothing originated as an adaptive behavioral response to biological nakedness which became a thermal liability during the Pleistocene ice ages. Findings from climatology and thermal physiology can reveal the prehistoric need for clothes as insulation from cold. While no garments have survived, archaeology yields evidence for clothing-related technologies in the paleolithic era (especially tailored clothes). The invention and improvement of clothes as protection from worsening weather conditions led to major technological innovations – toolkits with stone scrapers, blades, and bone needles. These technologies allowed hominins to conquer most of the world's environments and to finally enter the Americas from Siberia. Clothing was the most advanced technology developed by hominins in prehistory – and it is the only paleolithic invention that people still carry with them in the contemporary world.

Climate change was again relevant with clothes after the Pleistocene. Global warming made people change their clothes in many regions: They changed from wearing animal skins to woven fabrics. Textiles were a technological solution to the physiological problem posed

by sweating in warmer and more humid conditions. This effectively put the cloth into clothing, and production of textiles was a feature of neolithic agriculture. Clothes also acquired psychological and social functions relating to personal decoration and display, and also a new need to cover the naked body out of modesty. For these reasons, clothing finally came into fashion.

Evolution of Clothing

The oldest remains of clothing recovered by archaeologists are a few cloth fragments that date from 12,000 years ago at the end of the last ice age. However, clothing was invented much earlier, beginning perhaps a million years ago, and its prehistoric development was limited to populations in cool environments. Yet the habitual use of clothes is now almost a permanent and universal behavioral trait of humans: There is probably only one small group of Andaman Islanders in the Bay of Bengal who continue to live without any clothes. However, until recent historical times, many groups in warm climates wore little or no clothes on a regular basis. And while clothing now serves many psychological and social purposes, its origins reflect adaptive functions in the context of past climate change.

Origin Theories

The leading theories can be classified into three causes: display, modesty, and protection from cold. The first two suggest a universal human tendency to adopt clothes, which is refuted by ethnographic evidence from hunter-gatherer societies. Among many African and Australian groups, no garments of any kind were worn. For purposes of display and decoration, the naked body was adorned with paints, beads, feathers, tattoos, and scars (cicatrices). Early European explorers were often shocked by a complete absence of any need to cover the body for reasons of shame or modesty. Even in cold regions like Tasmania or Tierra del Fuego on the southern tip of South America, people used garments to ward

off the cold but otherwise they were naked (Gilligan 2008) – much to the astonishment of Darwin when he encountered the Fuegians in 1832 (Darwin 1839).

Protection from cold is the only motive consistent with all available data. A thermal model is supported by archaeological evidence despite a paucity of prehistoric clothing remains, and it allows the evolution of clothing to be delineated in considerable detail.

Scientific Evidence

The main sources of evidence are:

Ethnography – forager groups like Australian Aborigines, Andaman Islanders, Fuegians, and Bushmen (generally designated now as San peoples) were routinely naked prior to external contacts. Where clothes were worn, it was for thermal protection. In the case of the Bushmen, they had contacts with pastoralist groups in recent millennia and are often shown wearing loincloths, although early descriptions mention only the traditional antelope cape (kaross) worn in cool weather, used also as a rug and blanket (e.g., Sparrman 1785).

Biology – paleoanthropology can inform about the evolution of fur loss in hominins (Jablonski 2010), while thermal physiology delineates human cold tolerance and the physiology of clothing (Parsons 2014).

Climate science – paleoenvironmental research documents temperature regimes during the Pleistocene epoch from 2.6 million years ago to 12,000 years ago (Bradley 2015).

Archaeology – this encompasses data about the presence of hominins in cooler environments, technologies related to the manufacture of clothing, and artworks depicting clothes (Gilligan 2010).

Entomology – genetic studies of clothing lice can estimate when humans first adopted clothes, though the results relate more to the routine use of garments. Dates range between 84,000 and 107,000 years ago during the last ice age, or possibly as early as 170,000 years ago during the previous glacial cycle (Reed et al. 2015).

Prehistoric Technology

Hominins began to spread beyond Africa early in the Pleistocene, but they retreated from middle latitudes during the glacial episodes. From 800,000 years ago, *Homo erectus* was present in northern China throughout a couple of interglacials which also spanned a mild glacial period; clothing-related stone tools (scrapers and awls) were found at the cave home of Peking Man. From 400,000 years ago, hominins began to occupy northern middle latitudes during cooler phases and their toolkits contain more hide-scrapers, notably in the Mousterian industries of Neanderthals.

Homo sapiens evolved 200,000 years ago, but the earliest evidence for their presence outside Africa is 80,000 years ago in southern China. Signs of improved clothing technology appear in southern Africa during a cold phase 75,000 years ago, with stone blade tools and needles made from animal bones, which may have been used to make tailored garments. Eyed needles were invented as the global climate cooled again after 45,000 years ago, appearing first in southern Russia 40,000 years ago (Golovanova et al. 2010) and subsequently in northern China from 30,000 years ago (Zhang et al. 2010). Eyed needles appear a little later in Western Europe where conditions were milder; these quintessential clothing tools were common in the Solutrean industry around 22,000 years ago during the Last Glacial Maximum (LGM).

Simple and complex clothing refers to a distinction based on the thermal effectiveness of clothes and the technologies involved. Simple clothing has a single layer and is loosely draped, while complex clothing is fitted (or tailored) and can have multiple layers for added insulation. In terms of paleolithic technology, simple clothing requires scraper tools, whereas complex clothing also requires cutting tools (blades) and hide-piercing implements (awls and needles).

The archaeological evidence indicates simple clothing was invented multiple times by various hominin species from nearly a million years ago, whereas complex clothing was restricted to modern humans during the last glacial cycle. Only with complex clothes that fully covered the body

were decorative functions transferred onto garments, and the use of clothing then became more habitual. At the Russian site of Sungir near Moscow which dates to 26,000 years ago, two human skeletons were covered with thousands of beads made from the tusk ivory of mammoths. These beads were evidently sewn onto garments and arranged in two layers, documenting the presence of underwear (Bader and Bader 2000).

Textiles began to replace animal skins as the preferred material for clothes from the end of the last ice age 12,000 years ago, based on thermal properties of woven fabric which permit perspiration to escape more easily. Fabric was a practical and comfortable material for people who continued to use clothes in the warmer and more humid weather conditions. Production of fibers for textile clothes featured prominently in early agricultural communities (with wool, linen and cotton), which may have been an impetus for the transition to agriculture (Gilligan 2007). The oldest preserved woven fabrics were made from hemp-like fibers 12,000 years ago in Peru (Jolie et al. 2011), followed by linen fragments in Turkey around 9,000 years old (Hodder 2013).

Psychology

The evolution of clothing reflects the influence of biology and climate in prehistory, but psychological and social aspects have become more important during the historical epoch. Psychosocial factors are relevant to why people continue to wear clothes and also to how clothing has shaped modern human behavior and social evolution.

Motives for Wearing Clothes

Humans now take the thermal function of clothes for granted: People can choose warm apparel from their home wardrobes based on weather forecasts and purchase new garments in local shops based on the latest fashions. The main functions in the contemporary world are the contradictory motives of adornment and modesty: display and cover.

Fashion is almost synonymous with clothing. In sociology and dress studies, the role of clothing in adjusting appearance is paramount. However, a

focus on clothes as dress can distract from another fundamental function in the modern world: the paradox of needing to conceal the naked body from view.

Modesty likely began as a psychological consequence of wearing clothes, although its origins are shrouded in mystery. Initially it would have involved behavioral learning processes, with a combination of classical (Pavlovian) and instrumental (operant) conditioning. Nakedness was associated with exposure and vulnerability, and social reinforcement of covering behavior involved both rewards and punishment. The result was not only a new need for clothes as personal and social display but a sense of inadequacy and shame about lack of cover, transmitted to offspring as an independent psychosocial phenomenon. More intriguing, the social requirement for cover mandates concealment of sexual organs as a minimum.

Sexual shame and guilt likely emerged as a consequence of clothing, beginning with modesty. The initial psychological processes again would have been behavioral: Sexual behavior is associated with the naked body, especially the unclad skin surface. Once nakedness was sanctioned, sexuality became more problematic for society and sexual pleasure became socially subversive. Sexual display was increasingly transferred to clothes: Ironically, the main material instrument of sexual repression serves as a major means of sexual attraction.

Sexual repression happens within both the individual and society, and the crucial transition occurs when sexual restraint becomes useful and productive. This involves psychodynamic processes, notably sublimation (e.g., Valdrè 2014). The sexual drive is harnessed and transformed (often beyond recognition), providing a seemingly infinite and renewable source of energy to enhance cultural and intellectual activities and also to form intimate material attachments and promote technological innovation. Societies come to depend culturally and economically on these processes, and in this manner the modesty function of clothing becomes indispensable.

Modesty was established by the end of the last ice age among descendants of people who had

developed complex clothes. Archaeological evidence for modesty and sexual shame appears in artworks that depict people wearing garments covering the genitalia. One of the earliest is found at the 11,000-year-old megalithic site of Göbekli Tepe in Turkey: Images are carved on the stone pillars which show humans wearing loincloths. These were made from fox pelts, with fox bones among the commonest faunal remains at the site (Peters and Schmidt 2004).

Effects of Wearing Clothes

As cover and enclosure of the body and an agent for controlling sexuality, clothing has immense psychological ramifications.

Enclosure becomes generalized as a preference to construct external enclosures, separating the human world from the natural environment. One postglacial trend was sedentism, the shift from a mobile lifestyle to living in permanent settlements. Sedentism represents a withdrawal from open engagement with nature and it reflects the emergence of a dualistic mentality. The stone walls and enclosures of the early villages (like Çatalhöyük in Turkey) act as a form of externalized clothing, symbolic of a domestication process whereby humans as well as wild plants and animals were tamed and controlled (Hodder 1990; Ingold 2008).

Cover likewise is generalized as perception of the world as covered. The workings of nature are no longer apparent and immediately accessible to the senses; instead, they are perceived as concealed and accessible through a process of uncovering.

Science is the most productive expression of this covered perception of reality: an intellectualized desire to discover (dis-cover). Mind-body dualism and the development of geometry and mathematics are further products of a separation of the mind from the physicality of bodily existence in the present. Geometry and mathematics emerge as pure abstractions necessarily devoid of any temporal or sensual connection, as does the written word and the symbolic potential of language (Derrida 1974; Husserl 1939).

Materialism is another psychological trait accentuated among people who routinely wear

clothes. In becoming intimately attached to clothes as a fabricated material, a personal attachment is generalized to other materials and especially artificial fabricated objects. This spurs technological innovation and promotes an economic dependence on the production of material goods, visible in modern market economies and with the rise of consumerism. Conversely, naked foragers were distinctly disinterested in material possessions (e.g., Dampier 1729).

Human aggression and warfare is amenable to analysis as a psychological by-product of clothing. One of the challenges for evolutionary psychology is to explain why a taste for violence appears to be natural for humans. Rather than fabricating adaptive scenarios for this maladaptive trait, it can be understood as an outcome of the control and suppression of sexuality that accompanies clothing. Where sexuality becomes concealed and largely taboo, violence is sexualized through association as an evil or forbidden form of physical contact. As with all sublimated pursuits, it then acquires a capacity to deliver ostensibly nonsexual gratification, which has implications also for the philosophical – and psychological – problem of evil. This scenario can accommodate the troubling attraction of violence and the pleasure (and entertainment value) of war, without the ethological contradictions involved in portraying it as a vestige of humanity's animal nature. Moreover, it is compatible with the ethnographic and archaeological data, which point to an absence of warfare in naked forager societies and its relatively late prehistoric development among complex (particularly agricultural) communities after the end of the last ice age (Fry 2013; Pardoe 2014).

Social Evolution

The transition from egalitarian to hierarchical social structures based on wealth accumulation and inequality of access to resources is one of the major recent trends in human evolution. Its causes remain unclear and explaining its origins represents one of the great challenges for archaeology.

Hunter-Gatherers and Nakedness

Egalitarian social relations are a hallmark of naked forager societies. Sharing of food and material resources was actively promoted and defended, while any attempts by individuals to acquire or accumulate material wealth were actively discouraged and prevented. Egalitarian principles and group altruism probably evolved in hominins for adaptive reasons (Boehm 2012). Nonegalitarian societies emerged quite late – after the end of the last ice age – and only where clothes were present.

The routine presence of clothes acts as a barrier to casual tactile and sensual contacts between people. Among other primates, these tactile connections are almost constant from birth and serve to maintain social cohesion; they form the basis of connections between individuals and function as the main means of conflict resolution. In humans, cultural evolution is accompanied by a marked reduction in skin contact, whereas among egalitarian hunter-gatherers where little or no clothing is worn, tactile skin contact occurs almost constantly in infancy and childhood (Hewlett 2014).

Grooming and frequent tactile (including sexual) contacts in bonobos serve a key role in maintaining egalitarian group structure and forestalling violence (de Waal 1997). Once clothing is interposed between people, it prevents these routine skin contacts and discourages sexual encounters. Clothing thus sabotages the sensual basis of egalitarian social relations and promotes materialism and aggression, contributing to the collapse of egalitarianism.

Clothing and Social Complexity

The evolution of complexity has both a negative side (loss of naked egalitarianism) and a positive side whereby sexual repression and sublimation promote cultural development, culminating in the emergence of civilization. Freud saw repression and sublimation of the sexual drive as intrinsic to civilization (Freud 1930) although he neglected clothing, mentioning only how concealment of the body might enhance curiosity and the sublimation of sexuality into artistic pursuits. However, insofar as cover causes modesty and sexual guilt, clothing may play a more central role.

Cross-cultural research shows that clothing, modesty, and sexual restrictiveness correlate with various indices of complexity on a global scale (e.g., Murdock 1964; Stephens 1972). The civilizing potential of sexual repression and sublimation is underlined by the fact that the sexual drive is especially strong in humans: By any standards, *H. sapiens* is comparatively hypersexual (Ryan and Jethá 2010).

Conclusion

Clothing is a uniquely human innovation and its evolution reflects adaptation to unusual selection pressures. Biological nakedness may have first evolved as an adaptation to heat stress among bipedal ancestors, but it subsequently posed a survival challenge for hominins due to cold stress during the Pleistocene ice ages. Among various theories about the origin of clothing, those that claim a role for decoration or modesty as initial motives can be refuted by ethnographic evidence, whereas a thermal model is consistent with all available lines of evidence, including recent genetic studies of human clothing lice.

While there exists no direct archaeological evidence of prehistoric clothes in the Pleistocene, paleoenvironmental and physiological data can be harnessed to infer its development based on minimum thresholds of cold tolerance and the thermal properties of clothing. Archaeological evidence indicates that as hominins began to occupy cooler environments over the last million years, they developed technologies linked to the manufacture of clothing. These tools include stone hide-scrapers and blades for cutting hides, as well as awls and needles for sewing which first appeared during cold phases of the last glacial cycle from 100,000 years ago. Clothing was the most complex invention of the paleolithic era, and it promoted technological advances associated with the middle and upper paleolithic transitions.

The first clothes were simple loose garments which would have been discarded when no longer needed for warmth. The invention of fitted garments and multilayer assemblages – complex clothing – was restricted to *H. sapiens*. Complex

clothing differed from simple clothing in that once more complex clothing was adopted, it acquired nonthermal functions that encouraged the continued use of clothing after the end of the Pleistocene.

The postglacial onset of warm and more humid weather led to a major change in clothing material: the shift from using animal skins to woven fabrics. Textile garments became more common from the beginning of the Holocene epoch 12,000 years ago, and an increasing demand for textile fibers played a role in the transition to agriculture.

Modesty emerged as a psychological consequence of routinely covering the human body, and along with the transfer of decorative functions from the skin surface to using the surface of clothes for display purposes, modesty became a psychological motive for wearing clothes. Clothing is implicated also in the development of sexual shame and repression as uniquely human phenomena.

Sublimation of the sexual drive was a fundamental psychological process in social evolution and the emergence of civilization. The role of clothing in causing modesty and sexual shame thus makes it a key factor, but its psychological effects extend further and contribute to a host of modern psychosocial traits. These include separation from nature, construction of an enclosed artificial environment, the scientific mentality and the propensity for violence and warfare that dominates the historical era. In more ways than one, clothing is the fabric of civilized life.

Synonyms

Group leaders; Internal status hierarchy

Definitions

Coalition leaders take the responsibility of coordinating the efforts of group members. Such positions are both high-risk and high-reward and are therefore more likely to be occupied by men.

Introduction

Living in coalitional groups afforded many benefits to humans' hunter-gatherer ancestors, but in order to reap those benefits, individual members

of the group needed to be able to coordinate their efforts. This need for coordination likely led to the emergence of evolved mechanisms for leadership and followership. Individuals in leadership positions are likely to reap greater benefits from the efforts of the group but also incur greater risk. Given the high-risk, high-reward nature of leadership, it appeals most strongly to men, who owing to their minimal investment in offspring, benefit greatly from large investments in mating. Positions of leadership are likely to increase men's mating opportunities through the greater monopolization of the group's resources that women find desirable, as well as women's attraction to men who have earned high positions of status. As a result, men are likely to compete with one another, more so than women, for leadership positions. Below, this theoretical rationale is elaborated upon, and research examining the leadership tendencies of men and women, as well as the reproductive benefits bestowed to leaders, is reviewed.

Coordination in Social Groups

Humans are highly social animals that gain many benefits from living in groups (Baumeister and Leary 1995). Throughout evolutionary history, hunter-gatherers faced unpredictable environments that presented a variety of survival and reproductive challenges (e.g., preparing adequate shelter, navigating, hunting, fighting predators, attracting suitable mates, and nurturing offspring). Many of these problems are best addressed by groups and may be nearly impossible to deal with as a solitary individual. As a result, humans are likely to possess psychological mechanisms for promoting their membership in social groups.

Yet solving complex problems as a group is difficult unless the actions of individual members are well-coordinated with one another. This coordination may be best achieved by the presence of group leaders (Van Vugt et al. 2008). Research has indicated that evolved mechanisms for leadership and followership likely emerged within the Pleistocene period. Without such mechanisms among individuals, groups would not be able to so easily

coordinate efforts to solve complex problems, such as hunting large game, defeating predators, and raiding other groups for resources. Research consistent with the idea that humans possess such mechanisms for leadership includes that by Brown (1991) indicating that leadership is a universal characteristic of human societies. Additionally, research suggests that leaders naturally emerge in leaderless groups when a challenge arises that requires coordination (Van Vugt and De Crème 1999).

Sex and Leadership

Leaders of groups are in positions to gain increased benefits from group efforts. For example, leaders receive greater levels of prestige and dominance, as well as larger shares of resources acquired by the group. All of these benefits can be converted to increased mating opportunities. However, the benefits of leadership come at a cost. Leadership positions often entail many hardships associated with seeking and maintaining prestigious roles. Often it is a requirement of those seeking leadership to engage in dangerous acts of dominance, as has been observed in hunter-gatherer societies (Chagnon 1988). In pre-industrial societies, roughly 33% of men were reported to be killed while competing for status and resources (Daly and Wilson 1988). When status is threatened, men may be resistant to submitting to the threat as this would result in a loss of prestige as well as opening oneself up to attacks from others witnessing their submission (Felson 1982). However, status contests present a clear risk to physical safety, particularly when one is outmatched. Leaders also open themselves to risk by the very actions that define their leadership. Leading a hunting expedition or an attack on an outgroup entails large risks to those who make the first move (Hackman and Wageman 2007; Van Vugt et al. 2008).

Given the high-risk entailed in acquiring high-status and positions of leadership, it is expected that men will be more likely to gravitate toward such positions. In short, this is because men experience greater variance in their reproductive

outcomes and failing to compete for status and access to mating opportunities could result in reproductive oblivion. In contrast to women, men's obligatory investment in parenting is quite low, thereby freeing up time and energy for investment in mating. This incentivizes a male reproductive strategy that is oriented toward short-term mating with an emphasis on the quantity of mates.

In this context, women are a limiting resource because of their large investment in offspring and low reproductive ceiling. Given this large investment, women practice a more long-term oriented mating strategy that emphasizes mate quality, in particular, a mate's ability to help provision offspring with resources. The result of men and women's divergent reproductive strategies is that men must compete with other men to gain access to mating opportunities. A man's level of prestige or status provides a good indicator of their ability to provide access to resources desired by females. As a consequence, there are large incentives for men to compete for status, prestige, and positions of leadership that directly or indirectly increase their mating opportunities. Given the ability of one male to monopolize mating access to multiple females, some men face the prospect of reproductive oblivion. This leads to an increase in men's tolerance for risky behavior in the service of protecting or increasing one's status.

Leadership roles within hunter-gatherer societies are also male-oriented owing to the nature of the leadership tasks, sexual dimorphism, and the division of labor. With a largely egalitarian social structure, leadership in hunter-gatherers is largely task-specific and "earned" based on one's expertise and skill. Many tasks for which leadership is essential, such as hunting and warfare, are male-dominated tasks that require physical strength. Provided the physical differences between males and females, men were more likely to emerge as leaders in hunter-gatherer groups.

Still today, there is evidence that males are more likely to emerge as leaders in leaderless groups (Eagly and Karau 1991). Research has also shown that when asked to list characteristics for leaders, there was greater overlap with characteristics identified as descriptive of "men in general" versus "women in general" (Brenner et al.

1989; Schein 1973, 1975). Along similar lines, females are evaluated less favorably as leaders than are men (Eagly et al. 1992; Eagly and Karau 2002). Moreover, a meta-analysis provided evidence of a prejudice against women leaders, and that the preference for male leaders is heightened when the leadership role is a stereotypically masculine role (Eagly et al. 1992).

Leadership Benefits

Although leadership positions are risky in nature, many benefits come from the ability to control group resources and one's level of status and prestige within a group. For example, in tribal societies, research suggests that high-status men benefit from better nutrition (Chagnon 1990), thereby increasing their ability to successfully deter rivals and rise to positions of leadership. Across cultures, women also show a preference for high-status men with greater access to economic benefits (Buss 1989). Accordingly, individuals in high-status positions produce more offspring (von Rueden et al. 2011; Wilson and Daly 1985). These findings support the notion that intrasexual competition among men serves the function of increasing men's attractiveness to women by climbing the group social hierarchy (Buss and Shackelford 1997; Daly and Wilson 1978).

An examination of coalition leaders throughout history clearly illustrates the connection between leadership, status, and reproductive success. For example, Genghis Khan, leader of the Mongol Empire, has a long genetic lineage that still exists today. Research suggests that 8% of men residing within a large region of Asia are descendants of Khan and his male-line relatives (Zerjal et al. 2003) and that 0.5% of the world's population may be genetically related to Genghis Khan. In tribal societies such as the Yanomamö, high-status men typically have greater numbers of wives than low-status men in their polygynous society. Specifically, it has been documented that headman and warriors of the Yanomamö have more wives, more extramarital affairs, and more offspring (Chagnon 1988; Chagnon 2013). The

importance of high-status in acquiring mating opportunities is also well-illustrated by the plight of low-status men. For instance, in what is now considered northwest Germany, or Krummhörn, men of low status were four times more likely than men who were in higher social positions to have their genetic lineage extinguished (Klindworth and Volland 1995). Overall, these examples illustrate the connections between leadership and reproductive benefits for high-status males cross-culturally and throughout history.

Conclusion

As a social species, humans reap benefits from living in groups. However, extraction of such benefits requires coordination of efforts among members. Psychological mechanisms for leadership and followership were likely the result of a need for a leadership role to serve this function. Those who take on leadership positions tend to receive greater benefits obtained by the group. This includes tangible resources, as well as the indirect increase in mating opportunities as a result of high-status and resource access. Yet leaders must also tolerate greater risk, such as the consequences of physical dominance displays and conflict intervention. Given the high-risk, high-reward nature of leadership, and the task-oriented style of leadership that was pervasive among hunter-gatherers, men have been more likely to occupy positions of power and leadership. Indeed, provided the zero-sum nature of intrasexual competition for men, opting out of status competition is not a reproductively viable option. Evidence from both the modern labor market and tribal societies illustrates these principles in action, such that men are more likely than women to strive for positions of high-status and leadership.

Coalitional Hunting

Richard Holler
State University of New York, New Paltz, NY,
USA

Synonyms

Cooperative hunting; Group hunting; Hunting strategies

Definition

The collaborative effort to pursue and kill animals for food and other natural resources necessary for survival.

Introduction

Typical diets of the species of early humans, or *hominids*, have oscillated since the rise of the first primates. Although modern humans, often referred as *homo sapiens*, like ourselves, are omnivorous and are not restricted to eat only meats or vegetables, famine was always a lingering threat. As populations of humans expanded exponentially, demand for food skyrocketed while food supply plummeted.

Hunting for game larger than rodents and other smaller animals, such as bison and mammoths, satisfies the basic need for a larger band of humans to eat and survive. The endeavor to hunt larger animals is facilitated when done in groups rather than done by a single individual. Coalitional hunting not only provides more food for larger bands of humans, it also provides a crucial advantage to those who practice it over those who do not.

The physical and mental traits to better hunt and cooperate are embedded in human's biological and cultural evolutionary history. Traces of the effects of the extensive history of coalitional hunting on modern *homo sapiens* are what define archaic *homo sapiens* as *hunter-gatherers* and these effects are under the scientific scrutiny of evolutionary psychology.

Evolution of Coalitional Hunting

The culture of carnivores and predators are founded on their hunting instincts and skills. Although humans today do not hunt or scavenge on a basis, meat is a central feature of the human diet (Bailey et al. 2012). Modern humans are offspring of profound *homo sapien* hunters; many features that characterize a human, such as the ability to run long distances, having eyes facing forward, and having predilections to commit

kill, are reasons to claim ancient humans as hunter-gatherers. This *Hunting Hypothesis* acknowledges the natural athleticism of *homo sapiens* and of earlier hominids and implies that hunting alone was far more dangerous than hunting with others (Ardrey 1976; Bailey et al. 2012).

For millennia, humans have been hunting and eating meat (Ardrey 1976), but small game like rabbits, ducks, and wolves were not sufficient to sustain a hundred or dozens of humans, especially right after the ice age or other major climate changes (O'Neil 2014). Hunting larger game like reindeer, horses, and mammoths is an extremely difficult feat for one hunter; henceforth, adopting a new hunting strategy was in order.

Homo sapiens are not the only primates to practice cooperative hunting. Chimpanzees are known to sometimes coordinate themselves while pursuing prey (Melis and Semmann 2010). Scholars consider coalitional hunting to be rooted so deeply in human nature that it contributes to some physical and psychological differences between the sexes. Anthropologists are in general consensus that male *homo sapiens* predominantly had the occupation of hunting and most of which were kin (Wrangham 1999; Bailey et al. 2012).

For the Ache tribe in Paraguay, *persistence hunting*, a form of coalitional hunting, usually includes two to four hunters, which sometimes yields more than three times the amount of game killed per hunt with one hunter (Liebenberg 2008). In Europe, *homo sapiens* domesticated wolves and hunted with dogs, which may have played a major role on the extinction of lions, hyenas, mammoths, bison, and even the Neanderthals (Shipman 2015; Liebenberg 2008). Coalitional hunting was a powerful asset to human evolution that it may even be held accountable for the evolution of cooperation and social order (Melis and Semmann 2010).

Effects of Coalitional Hunting on Homo Sapiens

Coalitional hunting was more than a means to obtain a larger food supply (O'Neil 2014; Harari

2015). Saving time and energy, especially during times with limited hunting opportunities (Bailey et al. 2012), could aid the survival of much more than a single individual. From a gene's perspective via inclusive fitness, related individuals who receive any survival benefit are evolutionary advantageous (Melis and Semmann 2010; O'Neil 2014) and *any* individual involved with the coalition is likely to receive similar fitness benefits (Bailey et al. 2012).

Over time, coalitional hunting has granted humans with opportunities to advance their tools, strategies, and skills. Spears and other weapons became more sophisticated and individualized (O'Neil 2014); homo sapiens evolved the ability to throw projectiles with precision and accuracy; and social structures became more complex as populations increased (Melis and Semmann 2010). Moreover, the illusion for nature to select individuals evolved to the illusion for nature to select groups of individuals.

Species that practice planned and intricate hunting strategies is very likely to possess a mentality that permits higher order cooperation. Communication of information such as the locations of food, water, and lethal predators can separate the ones that survive from the ones that do not (Bailey et al. 2012). Homo sapiens acquired functional linguistic skills, which inadvertently expanded their populations (Harari 2015). The humans were not the only species to interpret and display communicative signals, domesticated dogs evolutionarily benefit with the ability to interpret symbolic behavior from their human masters (Bailey et al. 2012).

Other prestigious cognitive traits that are considered to have evolved from human's coalitional hunting nature include: memory for mapping their territories (Harari 2015); mental capacities to learn or become classically conditioned in order to predict when and when not to invest time and energy wisely (Bailey et al. 2012); the ability for the coalition members to focus their attention in unison; and even empathy and theory of mind (Moll and Tomasello 2007).

Coalitional Hunting and the Evolution of Human Psychology

As populations of humans grew exponentially, traits that engender higher social and emotional intelligence become advantageous adaptations. Evolutionary psychologists claim, even outside of homo sapiens, that there are psychological mechanisms that reduce aggression between group members and promote information-sharing (Bailey et al. 2012).

Evolutionary social psychology embraces what Robert Trivers called *reciprocal altruism* (Melis and Semmann 2010). Cooperation requires coalition members to practice specific policy orders and even morals (Bingham and Souza 2012). Psychological mechanisms that (1) aid in the determination of who contributed what and (2) to whom are the contributions addressed to reduce instances of free-riding and enhance perceptions of one's coalition or in-group; however, such perceptions may produce undesirable behavior and actions towards those who belong to an out-group (Wrangham 1999). Being ostracized, having negative reputations, and other certain punishments has a universal effect on species as social and intelligent as homo sapiens. Some evolutionary psychologists theorize that there are mechanisms that help prevent such dangerous consequences like ostracism (Melis and Semmann 2010).

The traits that characterize a charismatic leader such as decision-making, communication, and understanding other's limitations in order to assign proper roles may have originated in circumstances similar to coalitional hunts (Bailey et al. 2012; Moll and Tomasello 2007). Arranging into a populated social structure that obeys one or a group of leaders is a prerequisite of political policy. Paul Bingham and Joanne Souza (Bingham and Souza 2012) also recognized that a tribe's population is likely to be of a certain kinship, which serves a motivation to belittle outsiders or nonkin. Coalitional hunting, in essence, appears to meet the criteria as being a powerful and natural force that drove the cognitive revolution of humans.

Conclusion

Linguistic skills, memory for kin and other members and their roles, cooperation, and other social intelligence skills are at the forefront of both traditional social psychology and evolutionary social psychology. The attributes that compose a virtuous leader, the social infrastructures that constitute democracy, and a basis of morality may be of heritage of the ancient occupation of coalitional hunting. Evolutionary psychology, among other disciplines, accepts and examines the influential role of coalitional hunting on human psychology. The attributes that embody a prosperous hunting coalition during prehistoric times can still be observed today in modern human behavior.

Our hominid ancestors have been hunting as a means to obtain meat long before the evolution of the first primates. While evolutionary anthropologists and psychologists accredit coalitional hunting with both the mass extinction of other species including the Neanderthals and the humans' domination of the globe, further research awaits in order to establish the deep relationship between coalitional hunting and cognitive psychology (Bailey et al. 2012).

Coalitional Mate Retention

Nicole Barbaro

Department of Psychology, Oakland University,
Rochester, MI, USA

Definition

Mate retention behaviors performed by allies (solicited or unsolicited) that function to reduce the risk of partner infidelity.

Introduction

A long-term partner's sexual or emotional infidelity inflicts costs on both men and women, such as increasing the risk of contracting sexually transmitted diseases and inducing psychological distress, such as depression and anxiety. In fact, partner infidelity is the leading cause of relationship dissolution.

Men and women also incur sex-specific costs from partner infidelity, stemming from asymmetries in reproductive biology. Due to

internal fertilization and gestation occurring in women, ancestral men were uncertain that they were genetically related to their romantic partner's offspring. Thus, men are at risk of investing resources into genetically unrelated offspring. In contrast, ancestral women had maternity certainty. However, when they were rearing children (e.g., nursing), women relied heavily on male-provisioned resources. A woman whose partner is unfaithful risks losing partner-provisioned resources to another woman. Over evolutionary time, the sex-specific costs of a romantic partner's infidelity have produced sex-differentiated mate retention behaviors that appeal to opposite-sex mate preferences. For example, men (more than women) display their status and resources, whereas women (more than men) highlight their reproductive value and attractiveness (Buss and Shackelford 1997).

Given the costs associated with a romantic partner's relationship defection, individuals have motivation to perform "mate retention" – behaviors that minimize the risk of partner infidelity or defection. Individuals use several different mate retention strategies concurrently (Barbaro et al. 2015). One mate retention strategy individuals use is *individual mate retention* – behaviors that are performed by the individual without assistance from others (Buss 1988). Another strategy is when individuals recruit a close ally, such as a friend, to perform mate retention behaviors for them. Recruiting an ally to perform mate retention is a strategy referred to as *coalitional mate retention* (Pham et al. 2015a).

Evidence of Coalitional Mate Retention

Individual mate retention behaviors (i.e., behaviors performed without the assistance from allies) have been investigated by social and evolutionary psychologists for several decades. Empirical investigation of coalitional-level mate retention behaviors (i.e., behaviors performed with assistance from allies), however, went uninvestigated. Examination of instruments designed to assess individual-level mate retention behaviors provides peripheral evidence that individuals do

request the assistance from others to aid in their mate retention efforts of their romantic partner. For instance, a widely used measure to assess individual mate retention behaviors is the Mate Retention Inventory (Buss and Shackelford 1997; Buss et al. 2008). Two items in the Mate Retention Inventory (e.g., "had my friend check up on my partner," "got my friends to beat up someone who was interested in my partner") suggest that individuals do request assistance from others to perform mate retention behaviors. Another widely used instrument that assesses mate retention behavior is the relationship maintenance behaviors inventory (Stafford and Canary 1991). Although this measure does not directly measure coalitional mate retention, this inventory focuses on how cooperation and social networks promote healthy romantic relationships. These social network behaviors (e.g., "focus on common friends and affiliations") suggest that allies are instrumental for mate retention.

Further evidence of coalitional mate retention comes from historical and comparative documentations. For example, kings regularly recruited guards to protect their harem (Lad 2011). Additionally, many nonhuman species recruit allies for coalitional mate retention. For example, in lions, a coalition of males is more successful than a single male at defending sexual access to a female against rivals (Grinnell et al. 1995). Male macaques may form coalitions to overpower higher-ranking males to secure sexual access to fertile females (Bissonnette et al. 2011). Males of other species also sometimes form alliances with other males to defend sexual access to females as has been documented in cheetahs (Caro 1994), chimpanzees (Watts 1998), and dunnocks (Davies 1992).

Benefits and Costs of Coalitional Mate Retention

Coalitional mate retention can potentially overcome some costs of individual mate retention behaviors. Excessive use of individual mate retention may cause one's romantic partner to perceive them as overbearing, excessively jealous, and

mistrustful – which can reduce relationship satisfaction and, potentially, relationship dissolution. Individuals can reduce their partner's perception of excessive individual mate retention by employing coalitional mate retention. A person using coalitional mate retention can appear more trusting to their partner – for example, by having a friend accompany their partner to a social gathering where rivals may be present – and simultaneously reduce the risk of partner infidelity.

Employing coalitional mate retention could also increase one's perceived mate value to their romantic partner. Individuals mated to a less desirable partner are more likely to terminate a romantic relationship or commit infidelity (Shackelford and Buss 1997). Individuals can request that an ally advertise their positive qualities to their partner for them, thereby avoiding the costs of appearing narcissistic if they advertise their positive qualities themselves.

There are potential costs to coalitional mate retention. Individuals who recruit same-sex allies to perform coalitional mate retention are at risk for their ally poaching their romantic partner. Mate poaching may be particularly problematic when requesting coalitional mate retention – this strategy may signal to an ally that one's relationship is unstable and sometimes requires that an ally spend time with a romantic partner. Individuals who recruit opposite-sex allies to perform coalitional mate retention risk being a target of their ally's mate poaching attempts. Individuals sometimes befriend opposite-sex friends with the intention of mate poaching (Schmitt and Buss 2001), and friendship is one strategy individuals use to poach individuals away from their romantic partners (Mogilski and Wade 2013).

The Coalitional Mate Retention Inventory

Indirect evidence suggests that allies, such as friends, play important roles in helping individuals retain a romantic partner. Formal investigation of coalitional mate retention behavior began

the development of a measure designed to assess the frequency with which coalitional-level mate retention behaviors are utilized. Across two studies, Pham and colleagues (2015a) developed and validated the Coalitional Mate Retention Inventory using data- and theory-driven methods. Study 1 (Pham et al. 2015b) utilized an act nomination procedure (Buss and Craik 1983), asking 100 participants recruited via social media websites to report up to ten acts that they (or someone they know) asked their friend or relative to do to prevent their partner from becoming interested in someone else.

The acts obtained in Study 1 were then given to a separate sample of 387 participants recruited via Amazon's Mechanical Turk in Study 2. These participants were instructed to think of one heterosexual man and one heterosexual woman that they considered a good friend. For each friend, participants reported (1) how often they *requested* their friend to perform each behavior during the past year and (2) how often they believed their friend *performed* that behavior during the past year. Similar to the Mate Retention Inventory developed by Buss (1988), the Coalitional Mate Retention Inventory utilized the four-point scale (0 = *never*, 1 = *rarely*, 2 = *sometimes*, and 3 = *often*) to afford comparison between the two mate retention strategies.

The Coalitional Mate Retention Inventory includes 44 coalitional-level mate retention behaviors across seven tactic categories. The *Manipulation* component includes behaviors in which an ally deceives the partner into admitting (e.g., “got my partner drunk to see what my partner said”) or demonstrating (e.g., “tried to ‘hook up’ my partner with someone else to see what my partner did”) the partner's propensity to commit infidelity. The *Praise* component includes behaviors in which an ally says positive things to the partner and to others (e.g., “said nice things about me when my partner and other people were around”), thereby increasing the romantic partnership's desirability. The *Vigilance* component includes behaviors in which an ally watches the partner's behavior (e.g., “observed how my

partner acted around people interested in my partner”). The *Monopolizing* time component includes behaviors in which an ally spends time with the partner (e.g., “accompanied my partner to a party”). The *Therapy* component includes behaviors in which an ally strengthens the romantic partnership by repairing relationship problems and listening to relationship concerns (e.g., “told my partner how much I liked my partner”). The *Gifts* component includes behaviors in which an ally secures information about appropriate gifts for the partner (e.g., “told me what gifts my partner wanted”). The *Violence* component includes behaviors in which violence is employed against potential mate poachers (e.g., “hit someone who was flirting with my partner”).

Empirical Research on Coalitional Mate Retention

Concurrent strategies. Research investigated the frequency in which individuals employ coalitional mate retention as a function of individual differences, and contexts in which coalitional mate retention may be more readily utilized. Initial investigation of coalitional mate retention behaviors centered on whether coalitional mate retention is used concurrently with other mate retention strategies or used as a compensatory mate retention strategy. Previous research has demonstrated that, for men, individual mate retention behaviors are positively correlated with in-pair copulation frequency (Shackelford et al. 2006) – another type of mate retention strategy employed by males to prevent the risk of cuckoldry (Barbaro et al. 2015). This work suggests that individuals may use mate retention strategies concurrently to exhaust all potential mate retention efforts to reduce the likelihood of partner infidelity. Initial research to further investigate the relationships between coalitional mate retention and other mate retention strategies largely supports the notion that individuals use various mate retention strategies concurrently. Specifically, tactics of coalitional mate retention are positively

correlated with tactics of individual mate retention (Pham et al. 2015a), suggesting that individuals who deploy more frequent individual mate retention also deploy more frequent coalitional mate retention. Similarly, coalitional mate retention is positively correlated with in-pair copulation frequency (Barbaro et al. 2015), suggesting that individuals who deploy more frequent coalitional mate retention also copulate more frequently with their romantic partner.

Friendship quality. Because coalitional mate retention necessarily involves an ally, the quality of a friendship with an ally is likely to influence the frequency of coalitional mate retention. Research investigated whether requests of coalitional mate retention and unsolicited performance of coalitional mate retention differed as a function of friendship quality involving male and female friendships (Pham et al. 2015b). Results from Pham et al. (2015b) indicate that requests for coalitional mate retention are positively associated with the quality of friendships involving women (i.e., male–female friendships, female–male friendships, and female–female friendships) but are negatively associated with the quality of male–male friendships. The negative relationship between friendship quality and coalitional mate retention in male–male friendships may result because men, relative to women, inflict heavier retaliatory costs on mate poachers. For example, a man who poaches his male friend’s romantic partner risks potentially fatal retribution by the man (e.g., Daly et al. 1982). Coalitional mate retention may be less likely to be deployed between male friends who are especially close friends because poaching – and even the mere appearance of poaching – is a potent violation of male alliance.

Personality. Requesting coalitional mate retention is further influenced by individual differences in personality. Research has investigated whether the personality traits that predict performance of individual mate retention performance (e.g., Holden et al. 2014) extend to coalitional mate retention (Pham et al. 2016). Individuals lower in honesty–humility and higher in extraversion report less frequent requests for coalitional

mate retention. Men (but not women) higher in emotionality and lower in openness more frequently request coalitional mate retention, suggesting that coalitional mate retention might be employed more frequently by men who are less willing to communicate with their partner. It appears, more generally, that dishonest individuals are more likely to request coalitional mate retention, suggesting that coalitional mate retention – as compared to individual mate retention – is associated with manipulative and deceitful personality types (Pham et al. 2016).

Parity. Coalitional mate retention may be more frequently used by romantic partners who share offspring. Humans – unlike other primates – form long-term pair bonds. Men and women may remain pair-bonded following their child's birth to promote offspring survival by provisioning resources and providing protection from infanticide. Barbaro and colleagues (2016) documented that mothers and fathers perform more frequent coalitional mate retention than individuals without children. Specifically, men and women who share genetic children with their current partner more frequently request coalitional mate retention behaviors – across all seven tactics – from both their male and female ally than men and women who do not share genetic children with their current partner.

Conclusions

Coalitional mate retention behaviors are performed, solicited and unsolicited, by an individual's ally (e.g., a friend) to reduce the likelihood of a romantic partner's infidelity or defection from a romantic relationship. Coalitional behavior in the domain of romantic relationships was not an explicit area of study until Pham et al. (2015a) developed the Coalitional Mate Retention Inventory to assess the frequency with which individuals request coalitional mate retention from their allies and how often an ally performs coalitional mate retention unsolicited. Coalitional mate retention encompasses the intersection of mate retention behavior and coalitional behavior: two ubiquitous features of human life. Research has

begun to investigate relationships between coalitional mate retention and individual differences and dyadic process. There remain open numerous profitable avenues of research regarding coalitional mate retention.

Definition

Coalitional relationship: coordinated and cooperative action among two or more individuals against some third party or parties.

Alliance relationship: reliable co-participation in coalitional action over time.

Introduction

Coalitions are ubiquitous among humans and nonhuman primates (Chapais 1995; Cheney and Seyfarth 2008; Macfarlan et al. 2014; Patton 2000; van Schaik et al. 2006; von Rueden et al. 2008; Watts 1998). Coalitions are an important component of social dynamics by altering how power is distributed across individuals within and between groups and importantly affects fitness outcomes. Human warfare, politics, and economic behavior are coalitionally based and operate in a social landscape populated by like coalitions comprised of and connected by alliance relationships. Importantly, primates exhibit considerable variation in patterns of coalition and alliance formation. This chapter first details the key configurations that alliance relationships and

coalitional action can take among primate species. Then the importance of coalitions and alliances in humans will be addressed as well as their connection to the topics of the evolution of egalitarianism, hierarchy and status-striving, and cooperation in group-based conflict.

Coalitions in Primates

Considering the ranks that can be occupied by different individuals in a dominance hierarchy, three types of coalitions had been described in the literature: (i) conservative, (ii) bridging, and (iii) revolutionary (Chapais 1995). Conservative (i.e., all-down) coalitions are established when two or more high- or middle-ranked individuals attack a lower-ranked target (Chapais 1995). The outcome of this coalition does not upset the hierarchical order but rather preserves it. In nonhuman primates, such as in chacma baboons (*Papio ursinus*), high-ranked females living in female philopatric societies may not only receive support from other high-ranked kin within the matriline but also from females ranking immediately below (Cheney and Seyfarth 2008). By receiving support from female kin and from unrelated dominant females, high-ranked matrilines display greater cohesiveness, relative to lower-ranked families (Cheney and Seyfarth 2008). Thus, whereas low-ranked females should choose to support either a high-ranking unrelated female or her low-ranking kin, dominant females do not face such a social dilemma (i.e., the Anna Karenina principle; Cheney and Seyfarth 2008).

Intersexual conservative coalitions have also been described. For example, in multi-male polygynandrous societies, exhibiting long gestation and lactation periods, middle- or high-ranking females may seek support from a male against an invading or rival male due to the risk of infanticide or other expressions of sexual coercion (e.g., sexual intimidation and harassment; Lemasson et al. 2008). In olive baboons (*Papio anubis*), the number of male supporters or friends has been found to be positively associated with the rank of the female in the dominance hierarchy (Lemasson et al. 2008).

Male conservative coalitions in male philopatric societies differ from those observed among females living in matrilineal associations. Due to paternal uncertainty, kin-based cooperative mechanisms, such as kin selection and inclusive fitness, may not be sufficient for the formation of coalitions and alliances among males living in polygynandrous societies (van Schaik et al. 2006). Hence, cooperation based on mutualism, reciprocity, and/or biological markets (e.g., negotiating the exchange of commodities in accordance with the current demand and offer in the market) may allow the supporter of a high-ranking male to obtain benefits by preserving the hierarchy. Male chimpanzees (*Pan troglodytes*), at Kibale National Park, in Uganda, have been observed to collectively guard periovulatory females, tolerating the copulations of male allies, and preventing estrous females from copulating with rival males outside the coalition (Watts 1998).

Different from conservative bonds, in bridging coalitions, the association is constituted by a high- and a low-ranking partner against a middle-ranking target (Chapais 1995). By joining forces with a high-ranking member, the low-ranking member attacks and deposes the middle-ranking target and ascends in the hierarchy. Rank inheritance, the ascent in the dominance hierarchy based on the rank occupied by a relative, is a correlate of bridging coalitions (Chapais 1995). Rank inheritance has been described in both female philopatric societies (Chapais 1995) and in societies with female dispersal.

Besides the effects of maternal social status in rank ascent, intersexual bridging coalitions between nonrelatives require future exploration. Some evidence regarding female dispersal and male policing would support its occurrence. Immigrant female chimpanzees, for example, are frequent targets of aggression from resident females after joining a new group (Kahlenberg et al. 2008). Furthermore, the high urinary cortisol and low-status ranking would indicate the precarious condition experienced by immigrant females. Affiliating with a protective male allows dispersing females to decrease the risk of aggression when joining a new group (a similar process has

been observed in mountain gorillas; *Gorilla beringei beringei*; Kahlenberg et al. 2008). It is worth noting, however, that additional evidence is needed to determine whether females do ascend in rank as a product of male policing or if male protection of immigrant females is an expression of a bridging leveling coalition.

Finally, in revolutionary (i.e., all-up) coalitions, a high-ranking target is attacked by two lower-ranking members. Revolutionary associations have been described in male philopatric societies (Chapais 1995). For example, in captive chimpanzees, middle- and low-ranking males had been observed to join forces and depose a high-ranking male allowing the allies to rise in the hierarchy (Chapais 1995). However, in contrast with conservative and bridging coalitions in matrilineal societies, revolutionary coalitions are considered to take place infrequently (Chapais 1995).

More recent analyses have further subdivided the latter coalitional classifications into rank-changing and leveling coalitions. In rank-changing coalitions, individuals may depose or displace rivals in hierarchy. In leveling coalitions allies may not ascend in their ranks but rather temporarily gain access resources or receive protection during an agonistic interaction (van Schaik et al. 2006).

Coalitions in Humans

Across human societies, alliances and coalitional processes underpin systems of dynamic social power, affecting the establishment of both more and less egalitarian social arrangements. Further, coalitional phenomena are fundamental to understanding intergroup violence in humans.

Interestingly, coalitional processes have been hypothesized to contribute to the unique egalitarianism that characterizes most extant hunter-gatherer societies. A distinguishing feature of human political and social organization in comparison to that of chimpanzees is the variance in hierarchical power across societies. This variance has been described as the U-shaped trajectory of egalitarianism in human evolution (Knauff et al.

1991). Where at one end of the U, it is presumed that the last common ancestor of humans and chimpanzees was highly despotic and hierarchical, like extant chimpanzee populations. The lower trough of the U represents the political egalitarianism that characterizes extant foraging societies and likely the types of societies in which most of human evolution occurred, with the rising right end of the U representing the increasing hierarchy and despotism common to more complexly organized types of human societies, i.e., chiefdoms, archaic states, and civilizations. This model exhibits the precarious egalitarianism in foraging societies, which is underpinned by coalitions that function as leveling mechanisms that quell aggrandizing individuals from establishing themselves at the top of an incipient dominance hierarchy (Knauff et al. 1991).

However, coalitional support can grant as well as deny social differentiation by augmenting relative differences in power between individuals in potential contest competition. Evidence shows that coalitional support is an important predictor of multiple forms of social status among Tsimane men, a forager-horticulturalist group in the Bolivian Amazon (von Rueden et al. 2008). Social status is broadly defined as relative access to resources within groups. This influence of coalitional support on status differences is important considering how robustly status is associated with male fitness across a large sample of societies (von Rueden and Jaeggi 2016), which suggests that this status-fitness association is a possible human universal.

Coalitions are also a crucial element of human intergroup violence (i.e., warfare) and our understanding of this context as a cooperation dilemma. Namely, why should individuals take on personal risk of injury and death which benefits unrelated individuals in their coalition or in a larger group from which their coalition is derived? Despite the importance and interest in this topic, there is yet no consensus view regarding the ultimate evolutionary explanation that accounts for coalitional conflict.

Individual benefits to warriors do seem important in some contexts, such as for Yanomamö *unokai* (men who are recognized as killing an

enemy in conflict). In comparison to non-unokai, unokai have twice as many wives and three times as many children. This relationship survives a more robust statistical approach (i.e., Poisson regression with robust standard errors controlling for age, number of wives, and headman status; Macfarlan 2015), alleviating the criticisms often targeted toward the primary research.

In parallel, Patton (2000) shows that Amazonian Achuar and Quichua men are allocated status to the extent that they are perceived as distinguishing themselves in coalitional conflict, conditional on coalitional membership, and alliance strength, i.e., the condition that status allocators are likely to benefit from a warrior's behaviors in future conflict. Therefore, engaging in individually risky intergroup conflict can be an adaptive strategy for status acquisition in coalitional contexts.

Alternatively, costly coalitional conflict could result from the operation of group-structured cultural selection. Evidence includes the importance of social norms among the Turkana pastoralists of East Africa, which favor the punishment of cowards in large-scale battle raids and that hostilities should be directed toward other ethnolinguistic groups and never toward other Turkana territorial sections (Zefferman and Mathew 2015). Further, the cultural group selection model of cooperation is supported by assessment of cultural and genetic F_{st} measures, which gives the ratio of between-group variability in traits to total population variability. Notably cultural F_{st} is much greater between small-scale societies than genetic F_{st} , which suggests that cultural variation is better able to structure large-scale cooperation within societies in service of conflict against other ethnolinguistic groups (Zefferman and Mathew 2015).

Conclusion

Coalitions are a fundamental aspect of human and primate sociality. Among primates in general, they determine access to critical resources via contests within groups at the interindividual level. Though as identified here alliance relationships are expressed in varying patterns across species and for different purposes. Importantly,

these patterns also occur on a much larger scale in humans. However, the specific nature of the selection pressures operating to augment basic primate coalition formation to produce these patterns in humans is an active and a yet unsettled topic of research.

relating to frequency. Based on evidence from paleontological studies, cochlea seems to have been originated from the basilar papilla (hair-cell epithelium for hearing) of the stem amniotes such as lepidosaurs, archosaurs, and mammals. Further evidence of this statement is from a relative of the ancestors of land-living vertebrates, namely the “living fossil” coelacanth fish *Latimeria chalumnae*.

Inner ear; Organ of Corti

Definition

An important structure in the inner that is responsible for the analysis of sound.

Introduction

The cochlea is a snail-shaped structure in the inner ear and it is responsible to separate sound

Structure of the Cochlea

The cochlea looks like a snail and is comprised of fluid-containing compartments in the form of a spiral, and it contains the organ of Corti, which is the receptor for hearing (Chang and Khana 2013). In humans the cochlea is about 2.5 turns and if it is uncoiled it reaches a length of 3.1–3.3 cm. Its height in humans is 0.5 cm and it is similar in small animals such as the chinchilla. Together with the vestibular organ, the cochlea is enclosed in the temporal bone (Moller 2013). More than 15,000 hair cells in each cochlea are stimulated by the vibrations of the inner ear fluid. This motion causes the inner hair cells to produce electrical signals that are perceived by the brain as hearing (Balkany and Brown 2017).

Function of the Cochlea

Specifically, the cochlea separates the sounds according to the frequency so that different sound spectra activate different auditory nerve fibers. This sensory transduction takes place in the inner hair cells. The outer hair cells are active micromechanical elements that help to reduce friction on the motion of the basilar membrane. They, also, increase the vibration breadth of the basilar membrane for the lower intensities of sound and increases frequency selectivity. Also, the intensity of sound plays a significant role here because the frequency selectivity decreases when the intensity of sound is increased which in turn causes the cochlea to function in a nonlinear way. This nonlinear function delivers amplitude compression of the sounds before the innervation of

the auditory nerve. This process serves to code sounds in the auditory nerve based on the sound intensities (Moller 2013).

Furthermore, the function of the cochlea is to produce various kinds of sounds which are directed through the middle ear, triggering the tympanic membrane, which subsequently produces sounds known as the optoacoustic emission (OAE). This is, essentially, a sensitive microphone in the ear canal that records produced sounds (Moller 2013). Moller noted that there are many kinds of OAE such as: (a) the transient evoked optoacoustic emission (TEOAE), which is provoked by a momentary sound and produced by a reproduction of the traveling wave on the basilar membrane; (b) the spontaneous optoacoustic emission (SOAE), which is a continuous sound that is produced without any applied sound to the ear; (c) the distortion product optoacoustic emission (DPOAE), which is a measure of nonlinear alteration in the cochlea. This is provoked by applying two tones to the ear, and measuring the breadth of the tone difference (Moller 2013).

Evolutionary Status of the Cochlea

Based on comparative and paleontological studies, there is a possibility that a specific hair-cell epithelium for hearing (a basilar papilla) already existed in stem amniotes (lepidosaurs, archosaurs, and mammals) but was very small (Manley 2010). Evidence of this statement is based on a relative of the ancestors of land-living vertebrates, namely the “living fossil” coelacanth fish *Latimeria chalumnae*. Fritsch (1987) noted that the basilar papilla seems to be the precursor of the cochlea in mammals. Mammalian ancestors and ancestors of other amniote clades inherited a small basilar papilla for low frequency processing sounds (Manley 2000). Therefore, hearing high frequency sounds is not ancestral in the amniotes, nor in mammals but it was developed during the early evolution of therians (marsupials and placentals). According to Köppl (2011) the basilar

papilla is the organ of Corti in mammals, and it is homologous between birds and mammals.

The features of the therian cochlea was developed over millions of years, resulting in the loss of the lagenar macula – something which led to the decrease in endolymph calcium levels. Apparently, this led to a structural revolution of the auditory physiology of the cochlea (Manley 2017).

Based on comparative auditory research, the ears of birds and mammals are similar in function (see Dooling et al. 2007, on the processing of harmonic complexes on a number of different species), but are different in terms of precise temporal resolution for complex sounds – a trait that favors the birds (Dooling et al. 2002). Specifically, one major difference between mammals and birds is related to cochlear dimensions, which result in a frequency-dependent cochlear response delay (Dooling et al. 2007).

Organ of Corti

Another structure located inside the cochlea is the organ of Corti, which is composed of a specialized structure containing the hair cells together with their nerve endings and supporting cells. The organ of Corti is located on the basilar membrane and it organizes the auditory transduction. It becomes rigid by an arch of rods or pillar cells across its length, with the upper ends of the rods ending in the reticular lamina, which forms the chemical reaction between the ions in the fluids of the scala media and the scala tympani. The arch of rods is enclosed by phalangeal cells. The inner phalangeal cells enclose the inner hair cells, and the outer phalangeal cells (known as Deiters' cells) hold the basal ends of the outer hair cells. The outer phalangeal cells extend their phalanges to the reticular lamina. Various supporting cells such as Hensen's cells form rows inside the organ of Corti (Pickles 2012, pp. 28–33).

Moreover, the organ of Corti is covered by a gelatinous and fibrous fold called the tectorial membrane, consisting of molecules and collagens

known as tectorins (Pickles 2012, pp. 28–33). These tectorins have a significant role for the hearing process (see Richardson et al. 2011, for a review).

In order for the organ of Corti to generate sharply tuned traveling waves, and for the transduction of sound in general, certain electrochemical reactions must take place. This is done by creating a place where the cochlear scala is divided into the endolymphatic and perilymphatic spaces. Seemingly, the high positive standing potential and high potassium concentration of the endolymph seems to have a significant role in cochlear function for mechanotransduction and amplification of the traveling wave (Pickles 2012, pp. 52–57).

The cavity of the labyrinth of the inner ear is consisted of two compartments. The larger compartment, composed of the scala vestibule and scala tympani, runs the length of the system and is filled with perilymph. The other compartment is smaller and also extends throughout the length of the system. It is made of the scala media and is filled with endolymph (Pickles 2012, p. 52).

Endolymph and Perilymph

The endolymph, measured by ion-selective electrodes, is composed of a high level of K^+ (150 mM) and a low level of Na^+ (1.3 mM). The chemical composition is compared to the ionic composition found intracellularly. The endolymph and endocochlear potential are both created by the stria vascularis, a structure of the outer wall of the cochlear duct (see Pickles 2012, p. 54, for a review). The chemical composition of the perilymph, which is located in the outer fluid compartments of the cochlea, is similar to the extracellular fluid or cerebrospinal fluid.

The perilymph seems to be partially produced by transcellular transport of solutes from blood plasma, through the capillaries in the walls of the perilymphatic space. The K^+ concentration of the perilymph is 4–6 mM and the Na^+ concentration is 140–150 mM.

Conclusion

The structure and function of the cochlea has been briefly reviewed. The evolutionary development of the cochlea has, also, been reviewed. Additionally, the organ of Corti was discussed, as well as the purpose of the endolymph and the perilymph fluid surrounding the cochlea structure.

Definition

In intimate relationships, coercive control is a pattern of intimidation, isolation, and manipulation tactics used to gain and maintain power or dominance over a partner.

Introduction

Coercive control refers to a pattern of tactics, like intimidation, isolation, and manipulation, used by one or both partners in a current or former relationship. It is considered abusive on its own but can co-occur with physical violence or other forms of nonphysical abuse like emotional, verbal, and psychological abuse. Stemming from sociologist Michael P. Johnson's (2008) work on the typology of domestic violence, relationships involving coercive control and physical violence are classified in the scientific literature as intimate terrorism, patriarchal terrorism, or coercive controlling violence. The nature of these relationships mirrors what scholars have historically referred to as domestic violence, wife abuse, or wife battering, where sustained physical violence and psychological abuse are used by men against women. In relationships without a history of physical violence, coercive control is commonly called nonviolent coercive control or described as a form of psychological abuse in the social science literature. In general, violence and abuse against women is considered a major public health

concern in the United States, with about 1 in every 4 women experiencing some form of it in her lifetime (Centers for Disease Control and Prevention 2008). Male partners are much more likely than female partners to use coercive control and violence in heterosexual relationships. Relatively less is known about the nature, prevalence, and consequences of violence and abuse in same-sex relationships, but reports of coercive controlling abuse in same-sex relationships have begun to be documented (Frankland and Brown 2014).

Theoretical Explanations

Researchers of intimate partner violence have approached the study of coercive control and coercive controlling violence in heterosexual relationships from a variety of theoretical standpoints. Psychological and evolutionary scholars posit that mental illness and male proprietariness help to explain why some men may use violence and coercive control against women. Social learning theorists suggest that violence and coercive behaviors are learned within families and society, and feminist scholars believe that patriarchy and inequalities between men and women create the socio-cultural landscape and vulnerability for violence and coercive control against women to occur and be effective.

Evan Stark (2007) offers a conceptual model for understanding the four key elements of coercive control based upon multi-disciplinary research and direct practice with female survivors: violence, intimidation, isolation, and control. According to Stark, the violence used in coercive control may range in severity and frequency but is aimed at establishing and maintaining dominance and instilling fear. Partners use a variety of physical assault tactics, including but not limited to punching, choking, beating, raping, and using weapons or objects to produce physical harm and injury. Men may intimidate their partner in ways including but not limited to physical violence, for example by making threats and insults, creating shame and secrecy within the relationship, and stalking a partner or monitoring their daily activities. Intimidation and violent tactics

can also extend beyond the romantic relationship to involve or threaten close friends, family, and pets. A key feature of coercive control is isolation, as its success relies on women's inability to contact and receive support from others. Coercive controlling abusers may limit or deny access to friends, family, or even the general public. Last, coercive control involves the micromanagement of everyday life and control of resources, including one's access to money, transportation, and other necessities for independence and wellbeing.

Importantly, Stark (2007) emphasizes that coercive control is enacted in highly personalized and gendered ways. Indeed, given the intimate nature of romantic relationships, coercive controlling abusers are well-informed of their partner's daily routines, connections, and sources of strength and vulnerability that help make their entrapment of victims successful. In line with feminist scholars, Stark describes coercive control as gendered not only based on the typical perpetrator or victim but primarily based on patriarchal social norms and institutions that contribute to violence against women and the success of coercive control attempts. In fact, many coercive controlling abusers use gender as a tool of abuse, for example, by micro-managing household tasks traditionally assigned to women, or degrading and controlling a partner's appearance to diminish one's self-esteem and sense of identity as a woman.

Documented Consequences

Regardless of one's theoretical orientation, scholars across disciplines agree that coercive control has negative consequences for women, children, and families. A large body of research documents the particularly serious nature and impact of coercive control involving physical violence. When violence is aimed at controlling one's partner, it tends to occur more frequently, be of greater severity, and create more serious injuries than violence used situationally to resolve conflict (called situational couple violence; Johnson 2008). Coercive controlling violence is also associated with greater psychological consequences

than situational couple violence, including post-traumatic stress disorder, intense feelings of fear, and a sense of losing one's identity and self-worth. Women who leave coercive controlling and violent relationships remain at high risk for ongoing violence and intrusion by their former partners, particularly if they are mothers involved in coparenting (Hardesty and Ganong 2006).

Although less is known about nonviolent coercive control, it, too, appears to have damaging effects. Women with nonviolent but controlling, demeaning partners report having diminished self-esteem and symptoms of clinical depression (e.g., Lammers et al. 2005). Men's use of coercive behaviors in nonviolent relationships may also predict later use of physical violence. Johnson (2008) refers to this phenomenon as "incipient intimate terrorism." Despite these documented negative consequences, coercive control receives the most attention in research and identification and prevention efforts when it is coupled with physical violence. In fact, most researchers studying coercive control examine it only in conjunction with violence. Further research is needed to understand the nature and consequences of coercive control when used on its own to dominate a partner in relationships.

Conclusion

Coercive control has received increasing attention in research as a central component of abuse against women (e.g., Crossman and Hardesty 2018; Hardesty et al. 2015). Indeed, understanding coercive control helps to explain the damaging, long-term psychological impacts of abuse reported by women above and beyond physical abuse. Nevertheless, screening tools used today to identify women experiencing or at risk for abuse still rely heavily on reports of physical violence with less attention to psychological forms of abuse like coercive control. Thus, women in need of services and support may be overlooked by healthcare professionals, counselors, and other service providers, particularly when seeking help

to cope with or safely leave an abusive relationship characterized by nonviolent coercive control. Further research is needed to document the nature and consequences of coercive control, occurring both with and without violence, to help inform early identification, prevention, and intervention efforts that promote nonviolence and women's safety and wellbeing.

Definition

The survival advantages of coping with environmental changes through behavioral adjustments should have been a major force favoring the evolution of large brains.

Introduction

The cognitive-buffer hypothesis (CBH) is an attempt to explain why some animals have evolved large brains despite substantial energetic and developmental costs. The hypothesis, first formulated by Allman and colleagues (Allman et al. 1993; Allman 2000), posits that the essential role of the brain is to buffer animals against environmental variation. Assuming that this buffering capacity increases with the size of the brain, the hypothesis suggests that brain expansions might have been an adaptive solution to environmental changes.

The mechanisms by which enlarged brains are supposed to enhance survival are cognitive, and include inventing new behaviors and adjusting old behaviors to new situations (Fig. 1). Thus, a large brain would primarily reduce extrinsic mortality by facilitating the construction of plastic behavioral responses to novel or unusual

problems (Sol 2009). The most obvious example of the importance of the brain as cognitive buffer is found in humans, whose large brain and advanced learning abilities allow them to survive in places that otherwise would be inhospitable.

Evidence that Large Brains Evolved to Buffer Against Environmental Changes

The CBH is sustained in the finding that animals with disproportionally large brains (relative to body size) tend to exhibit lower mortality rates and live longer lives. Although necessary, this evidence is nonetheless insufficient to demonstrate the hypothesis as other mechanisms like delayed maturation and physiological regulation can also explain the above links (Deaner et al. 2003; Sol 2009) (Fig. 1).

An additional source of evidence for the CBH comes from the analysis of human-mediated introductions of animals outside their native ranges. If a large brain buffers individuals against environmental changes, the likelihood of establishing a persistent population in the new region should be higher for big-brained animals. This expectation has been confirmed for

reptiles and amphibians (Amiel et al. 2011), birds (Sol et al. 2005) and mammals (Sol et al. 2008) but not for fishes (Drake 2007). Within the new regions, many successful invaders thrive in human-altered environments, where enhanced abilities for behavioral innovation and learning are known to be particularly important (Liker et al. 2008).

In contrast, historical evidence showing that environmental variation has shaped brain evolution is lacking. However, some indirect evidence exist. In parrots, brain size is larger in species occurring in climate-variable environments (Schuck-Paim et al. 2008). In passerine birds, resident species exposed to seasonal environments tend to be more innovative and have larger brains than migratory species (Sol et al. 2010). In lemurs, relatively larger brained species tend to experience less variation in their dietary intake than indicated by the seasonality of their habitat (van Woerden et al. 2010).

Mechanisms Underlying the CBH

The CBH links two previously suggested ideas, that larger brains enhance the capacity of animals to modify their behavior and that behavioral

Cognitive Buffer Hypothesis, The, Fig. 1 Life history framework representing the cognitive buffer hypothesis (solid lines) and alternative mechanisms and feedback (dashed lines). According to the hypothesis, a large brain functions, and hence may have evolved, to buffer individuals from extrinsic mortality by facilitating the construction of plastic behavioral responses to novel or unusual conditions. This in turn may favor extended life span and

delayed reproduction, further increasing the benefits of plastic behavioral responses. Family living can also buffer individual against extrinsic mortality and select for larger brain to facilitate social interactions. The link between brain and lifespan reflects that other mechanisms besides a cognitive buffer may also explain why the brain is closely related to long-lived life histories (Modified from Sol (2009))

adjustments allow them to cope with many challenges animals encounter during their life.

The notion that behavioral adjustments are an important mechanism by which animals respond to environmental challenges is now well-established. Behavior not only mediates how animals interact with their environment but, by virtue of their plastic nature, can modify the interactions. New Caledonia crows, which have brains that are substantially large for their body size, are able to construct and use a variety of tools to extract insects from crevices. This allows them to exploit an important food opportunity that most other animals are unable to exploit. Learning is particularly relevant in facilitating the production of plastic behaviors. There is for instance evidence showing that training captive-bred animals to avoid predators can improve the success of reintroduction programs (Griffin et al. 2000).

While the importance of behavioral adjustments as response to environmental changes is unquestionable, the notion that larger brains enhance the capacity of animals to modify their behavior remains more controversial. A main concern is that because the brain is structured in functional distinct areas, mosaic evolution could potentially lead to brains of similar size by increasing different brain areas. This would imply that a brain can be large for very different reasons, making comparisons meaningless.

However, recent studies contradict the above criticism, showing that large brains are the result of increases in the brain areas more closely involved in general-domain cognition (Sayol et al. 2016). Moreover, there is growing evidence that animals with larger brains, relative to their body size, exhibit higher propensity to innovate behaviorally when facing new challenges. For example, the likelihood of observing innovative behaviors in the wild is higher in species with disproportionally larger brains in both birds (Overington 2008) and primates (Reader et al. 2011). Experimental support is also growing. By presenting 39 mammalian carnivore species with a novel problem-solving task, obtaining food from a closed box, Benson-Amram et al. (2016) demonstrated that species' relative brain sizes predict problem-solving success.

Artificial selection experiments in the guppy (*Poecilia reticulata*) have revealed that brain size can evolve rapidly and that increases in the brain bring associated improvements in learning, at least in females (Kotrschal et al. 2013). Finally, it is increasingly recognized that behavioral responses require more than cognitive abilities. For example, the ability to innovate behaviorally also depends on how morphology and physiology affect the ability to explore novel opportunities and the diversity of motor patterns needed to manipulate objects. However, the debate continues over why it is relative brain size and not absolute brain size what matters to be better at innovation and learning.

Environmental Scenarios Selecting for a Cognitive Buffer

Unlike other hypotheses for the evolution of large brains, the CBH does not assume any particular selective force. As a result, it allows integrating a variety of hypotheses for the evolution of large brains, both social and ecological. This is the strength and, at the same time, the weakness of the theory as it makes less explicit which selective scenarios should be examined to test the hypothesis.

In any case, the CBH does not deny the possibility that some selective pressures are more important than others. It should be noted that most current evidence for the role of enlarged brains as cognitive buffers come from the foraging domain. In mammals, the size of brain and adipose depots are negatively correlated (Navarrete et al. 2011), which can be interpreted as encephalization and fat storage being alternative strategies to buffer against starvation. This line of thinking has led to propose that large brains might have particularly been favored in highly seasonal environments, which force animals to cope with the harsh conditions during some periods of the year. In human evolution, for example, brain expansions have been associated with the transition from rain forests to more seasonal environments (Allman 2000). Inhabiting cold regions requires not only higher daily energy

requirements, but food must be obtained under difficult conditions (e.g., snow) and in a shorter daylight period (Roth et al. 2010). This should select for adaptations that enhance food acquisition and increase the accuracy and speed of decision-making (Roth et al. 2010; Sol et al. 2010). In agreement with the expectation, black-capped chickadees (*Poecile atricapillus*) from harsh northern populations tend to have larger telencephalic regions relative to body mass than those in the south, and outperform them in response to novelty and problem-solving ability (Roth et al. 2010). As already advanced, however, general evidence that environmental variation has selected for enlarged brains is missing.

Although features of the external environment may be important in selecting for larger brains, often it is not the environment itself but the way the animal interacts with it that really matters to understand how larger brains have evolved. Lefebvre et al. (1997) suggested that opportunist-generalist lifestyles, where individuals interact frequently with new food opportunities, should have been a major pathway toward greater encephalization on the grounds that learning is essential to exploit new food opportunities. Behaviorally, physiologically, and morphologically unspecialized animals are less constrained to develop new behaviors, thereby often relying on behavior to solve ecological problems. Indeed, there is evidence that large-brained animals are more generalists than small-brained ones, at least in birds (Overington et al. 2009; Ducatez et al. 2014; Sol et al. 2016), although it is unclear what is the cause and what the consequence.

Brain Evolution and Life History Theory

The CBH fits well with life history theory. Organisms whose fitness depends on a long reproductive life (that is, that prioritize survival over reproduction) need buffer adaptations to ensure high survival. A large brain could be one of these buffering adaptations. Large brains and enhanced cognitive abilities might thus be part

of a slow pace-of-life strategy to deal with environmental changes (Sol et al. 2016).

Considering brain evolution within a life history framework allows understanding why many species thrive with small brains despite the benefits of large brains. The brain is energetically expensive to produce and maintain, and hence energy invested in the brain cannot be diverted to reproduction. Moreover, developing the brain and the behavioral skills needed to survive takes time, which may force to delay the onset of reproduction (Fig. 1). Consequently, only long-lived animals may pay the costs of investing in large brains.

A life history perspective also helps understand why the brain has evolved so rapidly in some lineages, like primates and corvids (Fig. 1). A long life gives more time to explore and learn how to use new ecological opportunities, and increases the likelihood that individuals are exposed to changes during their life. As a result, the benefits of increasing brain size are higher in slow-lived species, generating positive feedback that may potentially speed up the evolution of enlarged brains. Likewise, longevity can favor a delayed onset of reproduction and promote family living (Covas and Griesser 2007). The social environment might in turn reduce mortality and facilitate an increase in brain size if, as the social intelligence hypothesis suggests, individuals living in cohesive social groups face higher cognitive demands than individuals living alone. These processes may again favor rapid evolutionary increases in the brain.

Conclusion

The CBH provides a sound explanation for the function, and hence the evolution, of large brains by proposing that large brains are part of a life history strategy through which animals buffer themselves against extrinsic mortality. While many aspects of the theory remain little understood, growing evidence shows that a large brain may actually buffer animals from environmental changes. In absence of historical evidence, however, whether the advantages of a cognitive buffer

may have been an important pathway toward greater encephalization lacks empirical verification.

If the brain functions to cope with changes in the environment, big-brained species should be less prone to extinction risk. This does not occur, however. Some big-brained animals like big apes and many whales are highly endangered. One reason may be that other factors beside the brain are important in putting species at risk of extinction. Long-lived species, like those with enlarged brains, tend to occur at smaller densities and recover more slowly from population crashes, and are thus quite sensible to hunting pressure. This warns us that like other adaptations, the brain is part of an adaptive complex that can be useful in some contexts but costly in others, implying that when it comes to the brain larger is not always better.

Cognitive Capacities

► Intelligence Testing

Cognitive Changes in Adolescence

Robert F. McGivern and Judy S. Reilly
Department of Psychology, San Diego State
University, San Diego, CA, USA

Human adolescence is the transitional period from caregiver dependency to the autonomy of early adulthood. During this extended period, both sociocultural influences and physiological actions of hormones play an important role. They act

independently and synergistically to influence neural networks in a manner that increases cognitive flexibility and reorients an individual's social interactions to the psychological and social complexity of adult society and sexual maturation. Behaviorally, these changes are manifested in the individual by increases in their self-awareness and that of the perspective of others, as well as increased interest in peer interactions and sexuality (Blakemore 2008).

At the onset of adolescence, the child already has a well-developed cognitive foundation. Piaget's sensorimotor and preoperational stages are completed, and the concrete operational stage is well advanced. Thus, at this point in development, a level of structural brain organization and cognitive complexity already supports the basic cognitive skills essential to adult social interactions. These skills include concrete logical thinking, adult levels of syntactical language complexity and comprehension, complex emotional comprehension and expression, and spatial and arithmetic abilities. During adolescence, the neural foundation of these skills is expanded in ways that support mating and parental behaviors, as well as social interactions with adults outside the family.

Piaget proposed formal operations as the cognitive stage that emerges during adolescence, which is characterized by an intellectual capacity for employing abstract logic and hypothetical thinking as part of problem-solving. Research over the past two decades has modified this view because cross-cultural studies of formal operations show that it is poorly developed or largely absent in a majority of adolescents and adults (Moshman 2009). Thus, adolescence is now viewed as a period of integration and expansion of existing cognitive systems. The current empirical approach to adolescent cognition focuses on how social interactions, hormones and sex differences, motivation, and self-regulation influence this remodeling reprocess (Spear 2013).

Influence of Hormones. The average age of puberty onset is 9–10 years, occurring approximately a year earlier in females. Menarche and spermarche occur about 2 years later when circulating estradiol and testosterone reach adult levels.

The process continues with the further development of secondary sex characteristics, such as breast development, fat deposition patterns, or beard growth, which extends the pubertal period to an average of 4 years.

Hormonal influences on adolescent cognition arise from the pubertal process, and their actions amplify behaviors related to social interactions but are not causal. For instance, adolescent elevations in circulating testosterone increase the likelihood of aggressive behavior in situations of social conflict, but they do not cause the behavior. Rises in hormone levels are gradual, and the process of puberty begins a year or two before there are manifest signs of hormonal actions.

The normal pubertal process has a significant amount of variability in its onset and duration, with onset ranging from 8 to 13 years and duration from 2 to 5 years. This has important implications for cognitive and behavioral influences of hormones, because although neural connectivity is influenced by hormone levels, brain growth during the adolescent period is an independent process. Thus, a brain exposed to adult levels of testosterone or estrogen at 11 years of age is not the same as one exposed to adult levels at 12 or 13 years. This creates an interaction between brain development, time of hormonal exposure, and sociocultural influence factors. The sociocultural influences, especially among peers, are partly mediated by the individual's stage of sexual maturation. These complex interactions contribute significantly to the wide range of socio-emotional behaviors observed in the adolescent population (Mills et al. 2014).

Brain Development and Adolescence. From a physiological perspective, the interaction between physiology and environment on adolescent brain development is part of a recurring, nonlinear pattern of postnatal brain growth (Huttenlocher and Dabholkar 1997; Thatcher 1997b). Between birth and adolescence, structural maturation of different cortical regions shows cyclical periods in the production of new synapses, followed by synaptic pruning associated with environmental stimulation. These proliferation-pruning cycles provide a basis for the environment to modulate brain development and brain

organization. For example, the prefrontal cortex connections with posterior cortical areas in the temporal and parietal cortex show a cyclical proliferation-pruning that closely follows the transitional ages of Piagetian cognitive stages before puberty. This suggests that these physiological changes underlie a reorganization of higher cortical processing related to changes in conceptual cognitive complexity exhibited at each stage (Thatcher 1997b). As new connections are integrated into existing neural circuitry, cortical gray matter continues to increase until it peaks during the mid- to late adolescent period (Blakemore 2008).

The same general process of synaptic proliferation and pruning unfolds during adolescence but with the additional influence of hormones. At the average age of puberty onset, there is a wave of synaptic proliferation in the connections between the frontal lobes and posterior cortical regions (Thatcher 1997a). Gray matter volume peaks in the frontal and parietal cortex at the average age when circulating hormones reach adult levels and then decreases over the next few years. In both cortices, the peak occurs around 11 years in girls and 12 years in boys. The volume decrease that follows the peak is generally interpreted as a reflection of synaptic pruning and reorganization associated with neural efficiency (Lenroot and Giedd 2010; Paus et al. 2010).

Changes in adolescent socio-emotional behavior may be a result of gradual strengthening and remodeling of connections between the prefrontal cortex and other cortical and subcortical areas. Important aspects of prefrontal executive function include an assessment of the emotional significance of a stimulus and taking the perspective of another. The brain areas involved include prefrontal connections with the anterior cingulate cortex, superior temporal sulcus, amygdala, and inferior parietal lobule. Together they form a social cognition network that shows evidence of structural reorganization during adolescence. Changes in this social network are thought to underlie adolescent mood lability, increased risk-taking behavior, and heightened self-consciousness (Blakemore 2008; Spear 2013). Imaging studies are consistent with this view. Studies related to emotional

processing in the social network show increased activity during adolescence in the orbital region of the prefrontal cortex and the anterior cingulate compared to younger children and adults (Monk et al. 2003).

Behavioral Correlates. Longer reaction times are found in adolescents for making perceptual decisions involving socially relevant emotional stimuli (Choudhury et al. 2006). This is consistent with other evidence showing changes in reaction time to identify emotional facial expressions in a task that relies on the prefrontal cortex (McGivern et al. 2002). At 10 years of age, reaction times to make a correct decision were similar in males and females. However, by mid-puberty, reaction times increased by 10–20% in both sexes, without any change in accuracy. In girls, this rise in reaction time was observed at age 11–12 and in boys at age 12–13. After this point, there was linear decrease through age 15–16 when reaction times were similar to that observed at 10 years of age. The sex difference in timing of the increase in reaction time suggests that synaptic proliferation at the time of puberty may be influenced by rises in gonadal steroids and that reorganization of prefrontal circuitry initiated by the rise in hormones leads to a decrease in cognitive efficiency.

These reaction time studies measure perception, not intellectual skills. With respect to full-scale IQ, large, cross-sectional samples in adolescents from ages 11 to 18 years do not show sex or age differences (Makintosh 2011). However, greater variability has been observed in female scores measured at 12 or 14 years of age compared to retest scores at 40 years of age. For males, greater variability was observed at age 18 compared to retest scores at 40 years of age (McCall 1977). Adolescent volatility in test-retest IQ scores was also observed in a study comparing individual performance and verbal IQ scores in males and females measured between 12 and 16 years of age with scores obtained in each individual 5 years later (Ramsden et al. 2011). Results showed changes in the performance or verbal IQ scores of some individuals that increased or decreased by a standard deviation or more. Although average scores for the two time points did not differ, there was a significant

increase in variability between the two tests. Imaging studies were also conducted in the same individuals at both testing ages. Results showed that the amount of change in verbal IQ score was positively correlated with changes in the density of gray matter in Broca's area, while the amount of change in performance IQ score was positively correlated with changes in the density of gray matter in the cerebellum. The pattern suggests that reorganization occurring in the adolescent brain at the time of testing influences performance. However, the group size at each adolescent age was not large enough to assess the role of puberty status, age of onset, or hormone levels at the time of testing in adolescence. These are important issues that remain to be addressed before a clearer picture emerges of how neural changes during adolescence influence cognition.

Sex Differences. In addition to the frontal and parietal cortices, male and female adolescents show structural differences in other cortical and subcortical areas that are associated with pubertal rises in circulating estradiol or testosterone (Mills et al. 2014; Paus et al. 2017). This raises structure/function questions regarding how these structural differences might relate to well-established cognitive sex differences found in adolescents and adults. An organizational role for early testosterone is well established in enhancing adult skills related to space relations, but only recently has an organizational role for androgens on the adolescent brain been proposed as well (Schulz and Sisk 2016). If hormones during puberty have organizational influences on cognition, are they acting to enhance existing cognitive sex differences, creating new ones, or having no cognitive effects? Well-established cognitive skills that favor males include tasks related to space relations, abstract visualization, and tracking movement. Those that favor women involve verbal fluency, episodic and autobiographical memory, and implicit memory for objects (Handa and McGivern 2015). Hormonal actions on brain organization during the perinatal period are an important influence on spatial skills favoring males, but early hormonal actions on the "verbal" skills that favor females are less clear. One possibility is that tasks favoring females become

more pronounced by pubertal rises in estrogen levels. Another possibility is that tasks that already favor males become enhanced by the rise in testosterone.

Two large studies approached these questions using cognitive sex difference tasks, imaging, and/or physiological measures. Herlitz et al. (2013) studied individuals at several ages during adolescence using a variety of cognitive tasks that show sex differences. The expected pattern of cognitive sex differences was present at the onset of puberty and did not change in magnitude over time irrespective of pubertal onset, age, or circulating hormone levels. However, a cross-sectional study found that the age of pubertal onset influenced mental rotation in males (Beltz and Berenbaum 2013) but did not observe age-related change in other tasks. The broad pattern indicates that cognitive sex differences are well established by the onset of puberty and that pubertal steroids play only a small role. Importantly, none of these studies were designed to address potential changes in social cognition due to hormones and age. Further research may yet show a differential role for pubertal hormones across adolescent age in organizing social cognition.

Key Idea

Cognitive development

Synonyms

Cognitive developmental science

Definition

The study of change across the lifespan in the mental action or process of acquiring knowledge and understanding through thought, experience, and the senses.

Introduction

Cognitive development encompasses behavior, cognition, and the brain from birth until adulthood. As such, it is a varied and complex discipline with many areas of study and numerous perspectives and theories. Below is a summary of the main theories of cognitive development that historically and currently have impacted the field. This summary is, of course, not exhaustive but provides a first look at the variety of the field. Next, the development of three major cognitive abilities is described: attention, memory, and language. These are also not exhaustive; any number of abilities could have been chosen. But, these three cognitions, and their accompanying behaviors, are understood very well from infancy through childhood and are broad cognitions used throughout everyday of life.

Major Theories

Piagetian Stage Theory

Jean Piaget (1896–1980) was a Swiss clinical psychologist in the early twentieth century who crafted one of, if not the, most influential theories of cognitive development to date. Piaget viewed children as “little scientists” who construct meaning in the world by interacting with it and testing their intuitive theories about how the world works. He described cognitive development as the movement between four distinct and independent stages of thought: sensorimotor (0–2 years), preoperational (2–6 years), concrete operations (7–12 years), and formal operations (13–adulthood). Children do not linearly or gradually move from one stage to the next; rather, each stage represents a distinctly different way of thinking about and interacting with the world. The sensorimotor stage is defined by exploration

of the world through strictly sensory means. In the preoperational stage, children become representational and able to represent concepts or objects with words and images. Concrete operations introduce logical thinking and the ability to engage in rudimentary mathematics. Lastly, children in formal operations are able to think abstractly and hypothetically about the world, what Piaget saw as the pinnacle of cognitive abilities.

Piaget argued that children hold theories or “heuristics” about how the world works. When a child encounters a new experience or piece of knowledge, learning occurs through one of the two processes: accommodation or assimilation. Accommodation occurs when information is encountered that requires a child to change their theory or heuristic of the world. The new information trumps what the child previously thought and requires a change in their theory of the world. Assimilation occurs when information can be worked into the child’s current theory of knowing about the world. It is through this process that children learn and are constantly updating their theory, like a “little scientist.”

This theory, and subsequent work supporting and contradicting it (known as neo-Piagetian), laid the groundwork for the modern study of cognitive development and has generated decades of debate and inquiry. As a general statement, Piaget was correct about much of cognitive development but probably underestimated the abilities of newborns and infants due, in part, to his limitations in research methodologies with this population.

Vygotsky’s Sociocultural Theory

Lev Vygotsky (1896–1934) was a Russian psychologist who formulated a theory of development incorporating biological, social, cultural, and historical elements. He was an influential figure in Russia and Europe, but not so in North America until the post-humous translation into English of many of his works in the 1960s. He is primarily known for two major concepts, tools of intellectual adaptation and the zone of proximal development, both of which tout the importance of cultural and social influences on children’s cognitive development.

Vygotsky defined tools of intellectual adaptation as cultural and technological tools and advancements that assist children in their cognitive capacities. He argued that the historical and cultural availability, or lack of availability, of technologies such as mathematics, language, formal schooling, etc. are significant determinants of the cognitive abilities achieved by children. For example, in modern America and Europe, it is not unusual for high school students to learn calculus, a truly advanced system of mathematics. This is a virtually impossible achievement for children who grow up as members of the Ache tribe in Paraguay, whose cultural tools do not include words for numbers above 3. Using systems of technology, cultures can accumulate knowledge and methods of learning enabling increases in cognitive complexity across time. It is not that people and children are inherently more intelligent today than in the tenth century, but becoming an astrophysicist is certainly easier if you grow up with computers in twenty-first-century France.

The zone of proximal development is Vygotsky's major contribution to how direct social learning and assistance can impact the cognitive abilities and behavior of a child. Vygotsky argued that children have a baseline capacity in any ability that they can accomplish on their own (e.g., a 6-year-old can successfully add and subtract single-digit numbers independent of assistance). There is also a limit to their abilities both with and without assistance (e.g., this same 6-year-old is incapable of long division no matter the situation). However, between these two extremes is a middle ground, known as the zone of proximal development, in which children can extend their abilities with the assistance of a more capable helper. For example, the 6-year-old can successfully add and subtract double-digit numbers, but only with the assistance of a parent or teacher. This zone is where assisted learning occurs; children have the ability but need help to consistently achieve. Vygotsky called this help "scaffolding." By standing on the scaffolding of an adult (or older child), children can extend their abilities and learn.

Information Processing

An information processing account of cognitive development focuses on change in explicitly measurable and quantifiable cognitive abilities. This perspective construes cognitive development as the increases in capacity or sophistication of both general and specific capacities. For example, working memory, the ability to hold information in mind and manipulate it for application to problem solving, is a general ability because it can be used to hold many different types of information in many different contexts. Capacity and speed of processing can be measured and will vary between individuals and across development. Examples of more specific abilities are verbal fluency, vocabulary, or reading comprehension.

One of the major goals of information processing is to define, quantify, and measure the importance of intelligence. Typically, intelligence is defined as two constructs in this perspective: first, crystallized intelligence and second, fluid intelligence. Crystallized intelligence abilities are skill based and learning dependent, such as vocabulary or social skills. Fluid intelligence abilities are considered to be more biologically based and constrained, such as speed of processing or inhibition. Often, fluid intelligence is known as *general intelligence* (*g* or *Gf*) and defined as the ability to use deliberate mental operations to solve novel problems. In other words, crystallized intelligence is information you can memorize; fluid intelligence are the abilities used to solve problems with this information.

Gf is considered a multifaceted variable that is deduced from the assessment and statistical and overlapping of other measurable abilities. Common measurements used to define *Gf* are attention, working memory, and perception/speed of processing. High scores on measurements of *Gf* are associated with better school achievement, mathematical prowess, and verbal abilities across the lifespan (for more info on fluid intelligence and development, see Primi et al. 2010).

Core Knowledge

Core knowledge can be seen as a neo-Piagetian perspective on development, in that one of its consequences is to refute Piaget's underestimation

of the cognitive capacities of infants. This approach to cognitive development emphasizes evolutionarily relevant classes of information or abilities that are present early in life and are then built upon throughout the lifespan (Spelke and Kinzler 2007). Major areas of core knowledge are number, objects/physics, and people. Infants are said to possess implicit understanding or knowledge of these aspects of the world either at birth or shortly after birth. Much of this work became possible with technological and methodological advancements that allow for cognitive testing of infants and assumptions about their cognitions and knowledge. Common paradigms utilize eye tracking (measuring where and for how long infants look at a given location or object) and habituation/dishabituation (a general measurement of looking time that allows for assumptions about whether infants can tell a difference between two stimuli). From these methods the cognitive world of infants has been shown to be much richer and more complex than scientists thought in the early and mid-twentieth century. Young infants seem to understand differences between small numbers (1 vs. 2 objects or 2 vs. 3 objects), intuitively understand Newtonian physics and how objects should behave in relation to each other and gravity, and prefer attending to people and speech.

Developmental Contextualism

Developmental contextualism is an interactive theory of development that grew out of evolutionary biology and incorporates all levels of analysis: genetic, neural, behavioral, and environmental. Many academics and researchers adhere to this perspective, the most influential of which is Gilbert Gottlieb. Gottlieb demonstrated that development cannot be considered in a vacuum, whether genetics and neurology in the absence of environment or social and cultural influences in the absence of genetics and neurology. This theory argues that the nature versus nurture debate, in which deterministic developmental processes such as genetics and environmental determinants such as rearing environment are pitted against each other, is a fruitless and wasteful enterprise. Development and complex functioning can only

be properly understood by adopting a multi-level interactive approach.

For example, Gottlieb (1991) conducted an experiment using incubating but unhatched duck eggs. Typical behavior upon hatching is to find the mother duck, by both sight and sound, and follow her, through a process known as imprinting. New hatchlings are able to do this with no apparent previous behavior or exposure, suggesting a purely genetically determined explanation for the behavior. However, Gottlieb demonstrated that even this basic behavior is dependent upon environmental input. During the time of incubation when the chick's auditory system is organizing, Gottlieb removed the upper portion of the eggshell and shined a strobe-like light into the egg. This disrupted the organization of the chick's auditory system in favor of devoting neural resources to the visual system, in response to the novel visual stimulus. Upon hatching, the chicks could not discriminate between a chicken call and their mother duck's call and failed to successfully imprint upon the mother. This suggests that the process of auditory discrimination and the ability to imprint is dependent upon auditory development and stimuli prior to hatching. Unhatched ducks hear their mother and their nest-mates and learn "what a duck sounds like." Thus, what appeared to be a straightforward genetic effect is dependent upon appropriate timing of environmental stimuli and the prompting of neural development.

Evolutionary Developmental Psych

A relatively modern perspective on cognitive development is the application of an evolutionary perspective, termed evolutionary developmental psychology. Founded by a diverse group of psychologists coming together from a variety of original backgrounds, most notably David Bjorklund and David Geary, this perspective acknowledges that evolution by natural selection does not simply begin working on the adult; it molds and shapes children and the process of development itself. Given that the human lifespan delays consistent reproduction until roughly the age of 15 years, there must have been selection pressures that warranted this shift in developmental timescale.

Furthermore, considering that a lengthy childhood is both metabolically expensive and physically dangerous, there must be substantial compensatory benefits to its existence. Evolutionary developmental psychology seeks to understand these selection pressures, the adaptations that arose from them, and how they impact the development of the modern child.

This theory recognizes two types of development relevant adaptations. The first one is deferred adaptations, which are behaviors or cognitions in childhood that serve to prepare the child for adulthood. Their benefits are deferred to adulthood. For example, female children display greater interest in infants and spend more time interacting with them than to male children, most likely in preparation for child rearing as adults. Second, ontogenetic adaptations are those that serve an adaptive purpose during childhood itself; they help the child survive or flourish during childhood. Aspects of infant and childhood memory have been theorized to represent ontogenetic adaptations, such as context dependence in infancy, increased recall for negative stimuli, and attention to and recall of faces (Sellers II and Bjorklund 2014).

Developmental plasticity is another hallmark of evolutionary developmental psychology, which contends that natural selection has, in some instances, selected for responsiveness to environmental inputs. For example, harsh and unpredictable early environments have been found to lower the age of menarche (first menstrual cycle) in girls. This is most likely the activation of a contextually sensitive mating strategy to help women achieve reproductive viability in an uncertain environment.

Cognitive Abilities Across the Lifespan

Attention

Infancy

Controlled and directed attentions are probably very difficult for an infant. They are experiencing a plethora of stimuli that all beckon for attention, deciding what to attend to, and having the

cognitive fortitude to sustain attention are quite difficult endeavors for an infant. However, there are stimuli to which infants preferentially attend. Faces (ovals and triangles, for their face like qualities), dynamic or moving stimuli, and high contrasts are all more likely to attract and hold the attention of an infant.

As mentioned previously, attention, in the form of looking time and eye tracking, are some of the only tools for making assumptions about the internal cognitive lives of infants. The introduction of these attentional paradigms caused a significant shift in how experimental psychology viewed infants. Since the 1990s, substantial experimental evidence forces the acknowledgement that infants active cognitive participants in their environment, holding expectations, memories, preferences, and assumptions about the world.

Childhood

As children age, they gain more sophisticated abilities in attention, such as the ability to consciously and explicitly attend to a particular stimuli. The ability to direct attention is tied to inhibitory abilities, to stop oneself from engaging in a non-relevant or desired behavior. For example, in order to attend to a teacher, a first grader must be able to inhibit their desire to talk to their friend or run around the room. In preschool (ages 3–5) inhibitory and attentional abilities are relatively poor, especially in comparison to adult-like functioning. The famous marshmallow test (Mischel 2014) is a wonderful demonstration of children's lack of inhibition. Children are given one marshmallow and allowed to eat it. But, if they wait and inhibit this desire, they will be given two marshmallows at a later time. Despite the obvious benefit of waiting, young children are notoriously poor at delaying gratification; they feel compelled to immediately eat the one marshmallow. While this may seem trivial, the ability to delay gratification and then attend to appropriate material are skills at the heart of success in the modern educational and corporate worlds. As children age, these abilities increase substantially into adulthood until individuals can be reasonably expected to attend school or work diligently for 8 or more hours per day.

Memory

Infancy

Infant memory is a difficult area of study as they obviously cannot directly respond physically or verbally to commands. However, through looking time measures and reinforcement/associative procedures, psychologists have concluded that infants do in fact possess implicit memory systems (and perhaps explicit), perhaps even more sophisticated than one would assume. At the age of 2 months, children can remember information for a few days, by 6 months their memory retention increases to about 2 weeks, and 1 year children can remember for up to 8 weeks. Children will have difficulty expressing these memories due to their limited language abilities, but their responses indicate reliable and accurate memory.

Paradoxically, adults experience *infantile amnesia*, the inability to remember events from infancy. So, even though infants themselves can be demonstrated to have memories, they are not retained into adulthood. In fact, most adults' earliest memories are from between 2 and 4 years of age. Many factors contribute to this lack of long-term memories from early life, such as the inability for infants to create memories using language, changes in neurological development, and infants' lack of explicit self-awareness.

Childhood

Beginning around the age of 2, children begin to display all of the memory systems also present in adults, explicit long-term memory, implicit long-term memory, and short-term/working memory. Explicit memories are those that can be consciously and purposefully recalled of both an episodic nature (e.g., remembering what happened at the park yesterday) and semantic nature (e.g., knowing that bananas are classified as a fruit) across days or years. Implicit memories are practiced physical activities (e.g., knowing how to ride a bike) or conditioned associations (e.g., Pavlov's dogs salivating to a bell). Short-term memory is a brief holding store for information, and working memory is this holding information in mind while using it for complex operations and problem solving.

Capacity for short-term and working memory reliably increases with age, reaching adult levels in the teenage years. Explicit long-term memory has no known capacity; humans can remember an immeasurably large amount of information. However, the accuracy of those memories can be assessed. Young children are more susceptible to false memories and to memory errors; they make many mistakes through by adding elements that were not present and forgetting elements that were. This is often an issue in child interviews or legal testimony, and careful steps should be taken not to influence a child's memory.

Language

Infancy

Infants are obviously not capable of sophisticated, representational language. However, they do engage in both communication and language learning. Crying is an infant's primary method of communication, and they will use different cries to signal different needs (e.g., hunger, discomfort, pain, etc.). Infants also observe language, attend to its noises and the faces of those speaking, and begin attempting to imitate at a very young age. Around 2–4 months of age, children will engage in "cooing," the elongation of vowel noises (e.g., "oooooh," "eeeeoo"). Between 6 and 10 months, children begin "babbling" the repetition of common consonant-vowel pairings in their native language (e.g., "babababa," "dadadada," "mamamama"). Many parents take these noises to be first words, especially "dadada" and "mamama"; however, they are not words meant to represent concepts or convey information. The infant is simply playing with and practicing the noises they hear in their world.

At birth, infants are capable of learning any language equally well, regardless of their racial or ethnic origins. This ability is supported by a host of neurological and behavioral characteristics that are genetically dedicated to language learning. However, they require the input of language within a certain timeframe in order to function appropriately. For example, at birth infants are able to distinguish between all phonemes in every language. A phoneme is the smallest unit

of spoken language sounds (e.g., /ff/, /ch/, /sh/). Some phonemes sound very similar and can be difficult to distinguish. Native adult speakers can recognize all the phonemes in their spoken language but do not have the same ability for other languages. Infants possess this ability for all languages but lose it around the age of 6 months for all languages other than their native one (Saffran et al. 2006). This process is known as perceptual narrowing and is a product of infants beginning to learn the expected language input from their environment.

Childhood

Around 18 months of age, children continue to increase their database of usable consonant and vowel sounds to the point of forming their first words. When speaking words with harsh, stressed syllables, such as the /t/ in “water,” children will often drop the unstressed syllable (saying “wawa” in place of “water”). Furthermore, until children learn the complex rules associated with language (syntax and grammar), they will use single words to convey numerous meanings. The words “water” can be used to request water, ask if something is water, or point out the presence of water. There are substantial individual differences in this process with some children experiencing a vocabulary spurt around the age of 18 months, some gradually acquiring new words, and others experiencing a later spurt.

The next step in language development is known as telegraphic speech, because it resembles the type of communication done over telegraph when users were charged by the letter. For example, a child might say “Mama go store” by dropping articles and helping verbs, instead of saying “Mama went to the store” or “Mama is going to the store.” Children then gradually acquire syntax, grammar, phonemes, and vocabulary through the preschool and school years. One commonality in language development throughout childhood and adulthood is the difference between receptive language and productive language. Receptive language, the number of words a person can understand the meaning of when

listening to them, is consistently larger than productive language, the number of words a person can appropriately use in their own speaking, across the lifespan. By 18 years of age, the average adult speaker has a productive vocabulary of around 150,000 words.

An important point to make about language learning in childhood is the existence of a sensitive period for language acquisition. Perhaps the most influential modern linguist, Noam Chomsky, theorized the presence of a Language Acquisition Device that helps young children acquire language (Chomsky 1986). While a bit of a misnomer, it is not an actual “device”; language research has in fact confirmed that the behavioral, cognitive, and neurological suites of abilities that enable language learning are most efficient early in life and gradually taper off in effectiveness throughout childhood. This is why learning a second language is more difficult for teenager or adults than it is for toddlers or elementary school students.

Conclusion

It is tempting to discount development, especially in the study of evolutionary psychology, as children are unable to engage in the adult behavior of reproduction that ultimately drives natural selection. However, childhood should be viewed as the “crucible of evolution” in that it served as an evolutionary bottleneck for survival and preparedness so that adaptive adult behavior could be possible. Therefore, development must be ripe with evolutionarily relevant adaptations of behavior and cognitions. In fact, if the study of evolution is how genetics interact with individuals and the environment, then perhaps there is no better place to study it than in development. From a non-evolutionary perspective, the study of cognitive development is critical for many areas of basic science (e.g., how genes interact with environment, how neurons grow and change, what is typical language development) as well as substantial application (e.g., developmental disorders, education policy, parenting practices).

Cognitive Ethology

Christina Stiso

Department of Philosophy, University of Calgary, Calgary, Alberta, Canada

Synonyms

[Cognitive science](#); [Ethology](#); [Study of animal minds](#)

Definition

A field that combines techniques from ethology and cognitive psychology to study animal cognition or animal minds.

Introduction

Giving a definition of “cognitive ethology” is difficult. In “Is Anyone a Cognitive Ethologist?” Colin Allen distinguished between two possible interpretations of what “cognitive ethology” might refer to (Allen 2004). It can be thought of, as many contemporary philosophers do, loosely as the general study of cognition in nonhuman animals (I shall follow the common practice in using “animal” to mean nonhuman animals). Marc Bekoff, a self-described cognitive ethologist, seems to have this more general idea in mind when he states, “cognitive ethology is the comparative, evolutionary, and ecological study of nonhuman animal minds including thought processes, beliefs, rationality, information-processing, and consciousness” (Bekoff 1995).

However, as Allen argues, this general conception ignores a number of important historical and methodological implications of the term. There is a core tension in the term between its constitutive parts; on one hand we have cognitive psychology, which pulls one toward the laboratory and controlled experiment, while on

the other we have ethology which values in situ observation of animals. Historically, it ignores the fact that the term was coined by Donald Griffin whose work focused, controversially at the time, on the conscious awareness of animals.

While the term “cognitive ethology” and the larger academic field it represents may be edged by some fuzzy borders, the study of animal cognition has made and will continue to make important contributions.

Text

History

Cognitive ethology is a combination of two separate traditions: ethology and cognitive science. Classical ethology is generally seen to be a continuation of the work done by Konrad Lorenz and Nikolaas Tinbergen. Their work encouraged observation of animal behavior within their natural environment. Tinbergen’s famous four questions (see Fig. 1), for instance, require that for any observed behavior to be understood, it must be placed in a context that includes both current and historical influences of the natural environment (Tinbergen 1963). On the other hand, cognitive psychology – which grew out of the cognitive revolution and general dissatisfaction with behaviorism in the post-World War II period – was highly experiment driven.

These two ideas were, at least in theory, brought together in a series of books and papers

beginning in the late 1970s where Donald Griffin coined the term “cognitive ethology” and laid the groundwork for the field’s eventual practice (Griffin 1978). Griffin’s initial work on the phenomenon of echolocation (a term he also introduced) in bats led to the controversial proposal that not only did animals have mental states comparable to those of humans, but that these mental states were valid objects of scientific inquiry. Griffin’s work was a critique of the behaviorist tradition, typically associated with B. F. Skinner, which dominated both American psychology and animal sciences in the early twentieth century.

Dangers of Anthropomorphism

One of the critiques that was leveled at Griffin is that by allowing animal minds as objects of research, one implicitly humanizes the animal and may be more likely to attribute complex, humanlike capacities where none actually exist. This is especially concerning in the context of evolutionary psychology as the cognitive continuity between humans and nonhumans is a central issue. These fears have been a concern within animal studies for centuries, but became formalized and popularized around the turn of the nineteenth century by Conway Lloyd Morgan in the form of Morgan’s canon:

In no case is an animal activity to be interpreted in terms of higher psychological processes if it can be fairly interpreted in terms of processes which stand lower in the scale of psychological evolution and development. (Morgan 1903, p. 59)

	Synchronic/Static: Looks at behavior in a point in time	Diachronic/Dynamic: Looks at behavior over a span of time
Proximate (How): Considers immediate influences on behavior	Mechanism (Causation) What are the mechanical or causal relationships that affect how the organism works?	Ontology (Development) How does the individual change over its lifespan?
Ultimate (Why): Considers role of behavior in the organism’s evolution	Adaptive Value (Function) How do the traits of the organism benefit it in terms of increasing fitness?	Phylogeny (Evolution) How does the species change over time, compared to others?

Cognitive Ethology, Fig. 1 Tinbergen’s four questions

There is currently debate over what, exactly, Morgan intended this statement to mean and how it should be used in the contemporary arena; however, the popular interpretation which has shaped much of contemporary comparative cognition studies is as a behaviorist Occam's razor, e.g., Griffin uses the cannon this way. We should, whenever possible, look for lower-complexity, nonpsychological, explanations for animal behavior and only resort to minds when behavior fails to enlighten us.

More recently, Sara Shettleworth's discussion of "killjoy" explanations in comparative psychology presents a slightly different take on the issue. A killjoy explanation is one that attributes the observance of complex behavior in an animal to a "lower" or nonmental process. Rather than being seen as boring, killjoy explanations should, in a sense, turn the tables and ask us to reexamine our assumptions about the complexity of human mental states. If an animal can exhibit behavior of humanlike complexity without relying on higher-order mental capabilities, it is at least possible that humans also rely on simpler, nonmental processes to exhibit these behaviors. Shettleworth claims that these killjoy explanations "contribute to a deeper, more truly comparative psychology" (Shettleworth 2010, p. 1).

Communication

Given the perceived importance of language to understanding the evolution of human cognition, it is unsurprising that a great deal of work had been done on communication in non-humans. Much of the modern work on animal communication and comparative communication can be linked back to Peter Marler. Marler's work on birdsong and primate communication, particularly his 1961 paper, *The Logical Analysis of Animal Communication*, laid the groundwork for much of the current literature (Marler 1961). Marler's model focuses on the receiver of a signal, using their behavior to indicate the content of the original message. While Marler's view is widely known and used, it is not the only one.

The popularity of Marler's model is due, partially, to its use by his successors. One of the most

widely cited studies on animal communication came from two of Marler's postdoctoral advisees, Dorothy Cheney and Robert Seyfarth. Their study on alarm calls in vervet monkeys (Seyfarth et al. 1980 and Cheney and Seyfarth 1980) shows that three distinct alarm calls are recognized by the monkeys – one for "eagles" and airborne predators, one for "snakes" and ground predators, and one for "leopards" and tree-dwelling predators – and that each elicits a different response.

The evolutionary implications of this came to a head in the debate between two groups. On one hand Marc Hauser, along with Noam Chomsky and W. Tecumseh Fitch, argues that the faculty of language can be seen in either a broad sense, FLB, which includes "a sensory-motor system, a conceptual-intentional system, and the computational mechanisms for recursion, providing the capacity to generate an infinite range of expressions from a finite set of elements" (Hauser 2002, p. 1) or a narrow sense, FLN, which includes only syntactic recursion. Further, Hauser et al. claim that FLN is the only uniquely human component of language and that, while it is ultimately an empirical question, FLN may have evolved for reasons other than human language, "for example, number, navigation, and social relations" (Hauser 2002, p. 1). On the other side of the debate, Steven Pinker and Ray Jackendoff have argued that the FLN-only approach is problematic (Pinker and Jackendoff 2005). They claim that it ignores a great deal of evidence from comparative anatomy and cognition, linguistics, and genetic studies that indicate at least one human speech and language gene that is not specific to recursion has been evolutionarily selected for.

Conclusion

Cognitive ethology is a young field which shows great promise of giving a better understanding on both human and animal cognition. The psychology (or at least cognition) of non-human animals is varied and complex, and the scientific study of this plethora will,

undoubtedly, be invaluable when thinking about human psychology, especially in an evolutionary context.

Cognitive Revolution, The

Sayantan Mandal
Concordia University,
Montreal, QC, Canada

Introduction

The cognitive revolution was an intellectual movement that began in the 1950s and exerted deep influence on psychology, linguistics, computer science, artificial intelligence, neuroscience, and philosophy. It was a reaction against the radical empiricist ways of behaviorism that had dominated the study of human and animal behavior since the early twentieth century.

Background

In the early twentieth century, psychology had wandered a long way from being the “study of mind” that William James had envisioned it to be. Quite the contrary, psychologists had all but given up on issues concerning the mind and the mental, focusing instead on behavior as responses to physical stimuli. The behaviorists argued that mental events, such as *beliefs* and *representations*, were not publicly observable. Since my internal beliefs, say “I like red cars,” are not objectively available to others for observation, independently of my introspective recollections, behaviorists argued that such concepts cannot be studied scientifically. Behavior, on the other hand, is very publicly observable and recordable. It is possible, for instance, to observe me repeatedly buying cars which are red and ascribe my decision to do so to similarly observable stimuli that reinforces my behavior, such as approving attitude of my friends and neighbors. As such recording observable behavior, documenting what factors in the environment (stimuli) correspond to them, and converting them to a behaviorist jargon were asserted by behaviorists to be the only means to bringing about scientific objectivity to the study of what living organisms do and

why (Miller 2003). Primarily an American phenomena, behaviorism had an overwhelming influence on experimental psychology. For many behaviorists, consequently, there ceased to be any meaningful dichotomy between *perception and discrimination*, *memory and learning*, etc. This, however, had the negative side effect of erasing any distinction between describing a phenomena (e.g., If dropped, a ball falls downward.) and causally explaining the precise mechanisms underlying said phenomena (e.g., the effects, and origins, of gravitational pull). In 1951, George Miller published *Language and Communication* (Miller 1951) a study of language and linguistic phenomena, acknowledging the well-established behaviorist bias of the time in his preface. Miller’s work, however, was much less radical in its behaviorism compared to B.F. Skinner’s soon-to-follow *Verbal Behavior* (Skinner 1957), which practically reduced language to operant-conditioned verbal behavior. It was Skinner’s book that sparked what has become, possibly, the most well-known criticism of behaviorism and one of the major manifestos of the cognitive revolution in the form of Noam Chomsky’s scathing review of Skinner (Chomsky 1959a).

Development

Behaviorism in psychology was a very influential movement in North America, dominating almost every aspect of the discipline and turning it into “a study of behavior.” The behaviorists had a narrow aim of predicting and controlling behavior, and in the case of psychologists like J.B. Watson, the latter took center field and equated all psychology with applied psychology. The motto of the methodological behaviorist was to deny all discussions of internal mental states or belief systems and focus simply on documenting observable behavior in order to isolate specific stimuli that could be used to either re-elicite, suppress, or modify said behavior in some shape or form. Watson’s insistence on using a stimulus-response approach resonated well with radical empiricists because of its reliance on the associative basis of all behaviors.

Allegedly, every behavior could be associated with some stimuli that could reinforce its learning. While the notion of “observable” was central to behaviorists in declaring their methodology as “science,” the history of science itself is rather sparse in endorsing such definitions of the term (Chomsky 1959a; Kuhn 1970; Whitehead and Russell 1912).

Watson’s influence was seminal in most aspects of psychology, flooding it with the standard stimulus-response approach; there still were notable exceptions found in E.C. Tolman’s “cognitive maps” and B.F. Skinner’s “functional behaviorism.” Skinner used a functional definition of stimuli and responses as eliciting/discriminative conditions and operant behavior (Skinner 1995), but not unlike stimulus-response behaviorists, much of his early work was focused on nonhuman behaviors. This was, directly and indirectly, a result of the theoretical failure of behaviorism in accounting for the complex cognitive functions found in humans (Miller 2003). As interest rose in explicating the biological basis of human cognition, and isolating the factor that creates a species boundary between *Homo sapiens* and other primates, the gaps in behaviorist reasoning started becoming more apparent. Having been banished from mainstream psychology for decades, the writing was on the wall for an oncoming paradigm shift in the study of mind and brain that was going to take *folk psychological* notions of *concepts*, *representations*, and *knowledge* with the seriousness it deserved and couch its defense in some form of physicalist naturalist framework, without regressing into a sort of Cartesian dualism.

New Beginnings

Breakthrough disciplines often bring about a transformation in science in general, and this was no less true of the cognitive revolution. A number of developments would ultimately result in the actual shift causing psychologists and philosophers to rethink what the object of inquiry in a scientific study of human nature

ought to be. This includes a growing realization of the shortcomings of the dominant paradigm of the day; the rise of then nascent disciplines like computer science, artificial intelligence, and neuroscience; and new developments in statistical and mathematical theories as well as breakthroughs in mainstream biology. The emerging developments in genetics and evolutionary biology were making it aptly clear that even in animals endowed with less complicated cognitive processes, a simple stimulus-response model could not account for their behavioral patterns. For instance, the works of biologists such as E.O. Wilson showed that an animal itself makes significant contributions toward curving out an ecological niche within which its experiential learning could take place. This contribution made by the organism is encoded in its genetic code, and a causal theory of behavior will then have to account for the ways in which the organism concerned interprets and represents its environment to itself (Wilson 2000). As exciting an adventure as behaviorism had been for psychology, it seemed poised not to succeed in attaining the goals it had set for itself.

Observing the obsession in psychologists of the day with recording a complete history of input stimulus and accompanying behavior, Chomsky (1959) writes:

Putting it differently, anyone who sets himself the problem of analyzing the causation of behavior will (in the absence of independent neurophysiological evidence) concern himself with the only data available, namely the record of inputs to the organism and the organism’s present response, and will try to describe the function specifying the response in terms of the history of inputs. This is nothing more than the definition of the problem. There are no possible grounds for argument here, if one accepts the problem as legitimate, though Skinner has often advanced and defended this definition of a problem as if it were a thesis which other investigators reject. The differences that arise between those who affirm and those who deny the importance of the specific “contribution of the organism” to learning and performance concern the particular character and complexity of this function and the kinds of observations and research necessary for arriving at a precise specification of it. If the contribution of the organism is complex, the only hope of predicting behavior even in a gross way will be

through a very indirect program of research that begins by studying the detailed character of the behavior itself and the particular capacities of the organism involved.

The premise of Chomsky's criticism here is rather simple – it is not enough to merely describe what an organism does and when, unless we have an account of how the circumstantial/environmental information of the event is filtered by the organisms' genetically limited processing abilities and the precise nature of the information extracted therein. In simpler words, if we observe that bats echolocate their ways around space, an explanatory account of the same should include the precise mechanisms that allow a bat to create sound waves and receive the echoed waves back in order to elicit spatial information from them. This ability is the bat's unique contribution to echolocation is independent of echoes as physical phenomena and cannot be inductively learned by a species unless they are born with it. What is difficult still, however, is coming up with such scientific accounts for infinitely more complex phenomena such as human mental processes (e.g., beliefs, desires, concepts, language, etc.).

The introductory lines of *Syntactic Structures* (Chomsky 1957/2002), a book that grew out of his initial attacks on behaviorism, aptly summarize Chomsky's intended alternative to approaching the psychological basis of mental processes:

Syntactical investigation of a given language has as its goal the construction of a device for producing the sentences of the language under investigation.... The ultimate outcome of [such] investigations should be a theory of linguistic structures in which the descriptive devices utilized in particular grammars are presented and studied abstractly.... One function of this theory is to provide a general method for selecting a grammar for each language, given a corpus of this language.

Unlike the behaviorists, Chomsky's rationalist approach is concerned less with attested patterns in behavior and more with the open-ended *creativity* with which children seem to manifest their linguistic abilities (Aarsleff 1970; Bever 2009; Chomsky 2009). This is reminiscent of Bertrand Russell's concern with how it is that human

beings, whose contact with nature is so brief and transient, come to learn so much of their environments? This would lead scientists of the day to look elsewhere in search of possible alternatives, and here Chomsky's seminal review of behaviorism comes to play an important role. Applying this general observation to linguistic phenomena, Chomsky asks how is it possible for a child to instinctively create new utterances to which it has never been exposed specifically, based only on exposure to a fraction of the possible sentences of a language. The conclusion that Chomsky drew from this line of thinking was already a staple in mainstream evolutionary biology (Mayr 1961, 1982) and amounted only to an acknowledgment that all epigenetic developments follow a trajectory that is genetically predetermined. In other words, to learn something properly, an organism needs to have at least a preliminary outline of what it is that needs to be learned and what constitutes evidence for such learning. Not unlike David Hume, Chomsky points out that though organisms no doubt derive much of their understanding of nature through experimental reasoning, that ability itself is something that they derive through the original hand of nature, and on this, they improve little to nothing throughout their lifetime.

All biological organisms are rather rigidly constrained in things that they can, and cannot, make sense of (Mayr 1982; Wilson 2000), and this constrain shapes and determines the way an organism would represent its knowledge of the world to itself. Psychologists of the day, however, were still reluctant to admit any notion of *representations*, as such talks were considered *mentalistic*, and being unobservable externally, mentalistic discussions were little more than mathematical obscurities to the behaviorist. This would change radically, however, with the rise of computer science and the growing realization that mathematical computations were in fact realized in nature on physical substrates. Here, at last, was a way to give a scientific expression within psychology to the link between cognition and behavior in a manner that was unlikely to fall short of biological complexity.

Computation and Cognition

The discussions so far have straddled various scattered bits and pieces of reasoning, with a common unbroken thread running through them – why do organisms behave the way they do, and what causes their behavior? The fundamental problem with behaviorism had been the problem of *causality*. It is not sufficient evidence of a causal relationship that event Y is often preceded by event X. Missing from such correlational observations, among other things, is the notion of levels of interaction that often lead to emergent phenomena. A scientific theory can only be evaluated at the appropriate level it is addressing, and while behaviorism flourished at locating correlations between X and Y, for example, its ability to tease apart whether the two events are correlated directly or as a result of intervening phenomena at levels not addressed by its stimulus-response methodologies was limited. This problem concerned not just linguistic behavior but held true for most issues concerning complicated cognitive phenomena of any kind. One of the first major empirical findings to put a finger on this issue involved Claude Shannon's information theory. Shannon's theory, based on Markovian processes, had an inherent allure for behaviorists and their stimulus-response methodology. Miller (1951, 1956b; Miller and Chomsky 1963) was among the first to illustrate that Shannon's theory was drastically lacking in explanatory prowess beyond elementary analysis of written sequences. Recounting his early efforts in this direction, Miller (2003, p. 1) writes:

But information measurement is based on probabilities and increasingly the probabilities seemed more interesting than their logarithmic values, and neither the probabilities nor their logarithms shed much light on the psychological processes that were responsible for them.

Miller's empirical findings would lead him to look elsewhere for explanatory accounts of cognition, and this would eventually lead him, and others, to Chomsky's syntactic theory. This shift in perspective, while slow, opened the door for reconnecting the two sides of the Atlantic and made possible meaningful collaborations with

research groups that were unaffected by the primarily American behaviorism. These would include, among others, Bartlett's works on memory in the UK, Jean Piaget's seminal research on child acquisition in Geneva, as well as A.R. Luria's foundational attempts at unifying the mind and the brain in Moscow. Being unaffected by the behaviorist aversion to abstractions, these researchers were willing to look beyond quantifiable behavior for explanations. Chomsky's syntactic theories seemed suited to become the strongest contender for an alternative framework, primarily because they were not statements of behavior but rather formal mathematical statements of cognition with *rules* of cognition proving the means for transformation of one cognitive state of affair into others.

This change in attitude would coincide with breakthrough developments in computer science. On the 10th of September, 1956, *The Special Interest Group in Information Theory* organized their seminal symposium at MIT, which directly led to some of the foundational concepts in computation and cognition being tabled for discussion. Newell and Simon (1956) discussed their *logic machines*, while Miller (1956) discussed the nature and organization of human memory architecture. Alongside these scholars, John McCarthy and Marvin Minsky (Minsky 1961; Minsky and Papert 2017) were laying the foundations of what would become *artificial intelligence*. Finally, while Chomsky was revolutionizing linguistics by demonstrating that language exploits all the precision of mathematics and explicating its computational nature (Chomsky 1959b, 1975), Bever, Fodor, and colleagues produced foundational research highlighting the cognitive subtleties of acquisition (Bever et al. 1965, 1969). Miller (2003) writes that computer scientists like Newell were primarily invigorated by Chomsky's exposition of the algorithmic beauty of language, as it was finally making available for formal mathematical investigation one of the most complex human behaviors. Other related developments included Szikali's experiments on perception and processing and Birdsall's work on application of signal detection theory to perceptual studies.

The major formal recognition of something akin to a scientific revolution involving multiple disciplines would come with the Sloan Foundation's interests in funding extensive research into what was by now being referred to as the *cognitive sciences*. Following the establishment of the cognitive studies group at Harvard, information-processing psychology at Carnegie Mellon, and an international meeting at MIT in 1974 organized by Massimo Piattelli-Palmarini bringing together biologists like the Nobel laureate Salvador Luria and linguists like Chomsky and Lenneberg, the foundation facilitated the formation of a highly interdisciplinary committee to summarize the state of the art in cognitive science. Miller (2003) writes that the driving concepts behind the emerging areas of research were summarized in a hexagonal figure, with the six corners representing the six major fields that would contribute expertise, while the lines joining them stood for an interdisciplinary methodology combining the tools of the disciplines. Thus, the union of computer science with the computational interpretation of linguistic phenomena would lead to computational linguistics, while computational methodologies would model neural functionings elucidated by neuroscientists to create cybernetics. The Sloan Foundation accepted the report in 1978 (Miller 2003), and subsequently, funding was made available to various universities for recruitment of scholars and facilitation of scholar mobility, seminars, and collaborations. This directly resulted in an outburst of scholarly works that pushed the limits in a multitude of disciplines and brought about methodological

paradigmatic shifts in all six disciplines. Linguistics rapidly matured from being the red-haired stepchild of philology to a proper scientific study of a biological phenomenon (Massimo Piattelli-Palmarini coined the term *biolinguistics* in 1974 to describe this emerging new field); philosophers left their armchairs and indulged in sophisticated empirical pursuits, while computational sciences established once and for all that computation was more than a mathematical convenience and constituted a fundamental natural phenomena. The study of thinking was no longer the domain of metaphysics and speculation, and the human mind was ready for a naturalistic inquiry into its functional and architectural limitations (Fig. 1).

Impact and Aftermath

The impact of the events that unfolded in the 1950s, and through the 1960s and 1970s, has been profound enough that the series of events have been termed *the cognitive revolution*. While the term revolution is prone to imply a somewhat violent detachment from all things past, a number of scholars have pointed out that in reality, it was more of a return to unanswered questions and unexplored problems yesteryears (Chomsky and McGilvray 2009; Fodor 2001). The cognitive revolution was primarily driven by a need to better understand the nature of information and the role of a biological organ, the brain, in packaging and storing it in a fashion that could feed cognitive processes. The foundational frameworks were laid by the works of Noam Chomsky

Cognitive Revolution, The,
Fig. 1 Cognitive science in 1978. (Source: Miller 2003)

(1965, 1975, 1980, 2002), Jerry Fodor (1975, 1981), David Marr (1982), and Eric Lenneberg et al. (1967) among others. Chomsky’s attack on behaviorism opened the door for a return to the old questions concerning universality of the human mind. In *Cartesian Linguistics*, Chomsky and McGilvray (2001) notes that the idea that there must be something universal about the structure of the human mind, and its unique abilities including language, date back to Descartes and featured prominently in the works of the Port Royal Grammarians. Chomsky’s formalist investigation of the information structuring of natural languages (Chomsky 1975), as well as his works on formal languages and logic (Chomsky and Schützenberger 1959), helped firmly establish the need to approach the functioning brain as a mathematically describable information processing system. Early research in computer science would then help establish that computations are, indeed, executable on physical substrates further lending credence to the plausibility that the brain could really be something akin to a computer. It was, however, the philosopher and cognitive scientist Jerry Fodor who would propose the most impactful analysis of the mind as a computer with his series of expositions of *the computational theory of mind* (Fodor 1975, 1981, 2001). Fodor argued that mental states, such as beliefs and desires, are relations between individuals and mental representations. He maintained that these representations can only be correctly explained in terms of a language of thought (LOT) in the mind. Furthermore, this language of thought itself is an actually existing thing that is codified in the brain and not just a useful explanatory tool. Fodor adhered to a species of functionalism, maintaining that thinking and other mental processes consist primarily of computations operating on the syntax of the representations that make up the language

of thought. For Fodor, significant parts of the mind, such as perceptual and linguistic processes, are structured in terms of modules, or “organs,” which he defines by their causal and functional roles. These modules are relatively independent of each other and of the “central processing” part of the mind, which has a more global and less “domain-specific” character.

Likewise, the neuroscientist David Marr was a pioneering influence in furthering the understanding of the biological basis of information processing (Marr 1970; Marr and Thach 1991; Marr et al. 1991). Marr’s seminal book, *Vision* (Marr 1982), argued for what is often referred to as *the tri-level hypothesis* – one must understand information processing systems at three distinct, complementary levels of analysis (Table 1).

The convergence of the sort of psychological nativism and computationalism advocated by Chomsky, Fodor, and Marr has been influential in, some senses, completely refocusing the research questions that concern scientists involved in understanding the biological basis of cognitive functions (Bever 1970; Bever and Poeppel 2010; Carey 2009; Embick and Poeppel 2015; Fodor 1998; Hauser et al. 2002). A complete review of its influences is beyond the scope of this chapter, but briefly, its effects have been dominant in four major strands of emerging research – the evolution of complex cognition, the realization of highly formal computations on physical/biological substrates, the constraints on such computations and their realizations stemming from general laws of nature, as well as in more applied researches into bioinformatics and artificial intelligence.

The discussion of evolution of cognitive abilities has a long and complicated history in the scientific literature. While curiosities and

Cognitive Revolution, The, Table 1 Marr’s tri-level hypothesis

Level	Description
1. Computational level	What problem does the system solve?
2. Algorithmic level	How is the problem solved, and what representations are used?
3. Implementational level	How is such a system physically realized?

speculations about the universal nature of the mind can be traced back to Plato (cf. *Plato's Problem*, in Chomsky and McGilvray 2009), with significant contributions by Kant, Descartes, and Hume (Chomsky 1959a, b), discussions of evolutionary origins of such abilities like language were declared taboo by the *Société de Linguistique de Paris* in 1866. With the advent of the cognitive revolution, however, a naturalist framework for such discussions was made available that did not have to regress to Cartesian dualism (Chomsky and DiNozzi 1972). This effect was not limited to linguistics in particular either, as the fundamental basis of the revolution was predicated upon the issue of mental representations. A representational system, linguistic or otherwise, is an algebraic system of symbolic variables (Gallistel 1981). The symbols are the representational primitives that form representations that are *isomorphic* to another system, the represented system. The isomorphism implies that the mathematical relations that hold between the symbols bear a similar form to the ones holding between the things being represented. Because the forms of the relations that the variables enter into are the same between the two systems, it ensures the validity of the conclusions drawn about the represented system through an analyses of the symbols of a representational system. Computational processes are algorithmic instructions that dictate the manipulation of representational symbols, leading to generativity. Accordingly, Gallistel and King (2009) have argued that the ability to represent numbers, and to recall them from long-term memory, is the most important mechanism that underlies higher cognition. In a similar vein, many researchers argue that a science of cognition is essentially the science of representational systems and their inner workings (Gallistel 2001; Marcus 2003).

The exact nature of the evolutionary process that led to such computational representational systems is still a hotly debated topic. While Pinker and colleagues have argued that the computational mind is a result of adaptation through natural selection (Pinker 1997; Pinker and Jackendoff 2005), yet others have criticized the adaptationist approach (Fitch 2005; Fodor 2001; Fodor

and Piattelli-Palmarini 2011; Hauser et al. 2002; Hauser and Spelke 2004). The growing interest has contributed significantly to the rise of evolutionary psychology as a major scientific discipline, with its insistence on a massively modular mind that is the result of specific adaptations to different needs (Pinker 1997). While maintaining its commitments to computational-representational theories, the evolutionary psychology approach has nonetheless attracted criticisms directed both at its conception of modularity and computationalism from other computationalists (Fodor 2001).

Effects of the cognitive revolution have been also prominently felt in neuroscience and psychology, especially with the advent of easily accessible neuroimaging tools. The ease of observing the functioning brain in action has led to a plethora of imaging studies that have shed light on the many intricacies involved in cognitive processing (Bosker 2016; Chow et al. 2014; Tettamanti et al. 2002, 2009; Wilson and Iacoboni 2006; Xiang et al. 2009). As useful and insightful as imaging studies of various kinds have been, however, the cognitivist perspective has exerted an even greater influence over theoretical neuroscience. For instance, David Poeppel and colleagues have argued in a series of influential publications that in order for cognitive neuroscience to be successful, appropriate linking hypotheses must be posited between cognitive and neural phenomena (Bever and Poeppel 2010; Poeppel et al. 2012). Because neuroscience and formal cognitive investigations operate on different sizes of conceptual granularity, the authors argue that there is no direct translation of phenomena from one domain in terms of the lexicon of the other. Two important factors are pointed out – (i) *the granularity mismatch* issue points out that the phenomena that concern the two disciplines, and their primitives, are not similar in their conceptual granularities, and (ii) *the ontological incommensurability problem* is a reminder against greedy reduction of cognitive primitives to neural substrates (Embick and Poeppel 2015; Poeppel and Embick 2017). Likewise, Krakauer and colleagues have argued that in order to attain a properly explanatory

account of the neural basis of cognitive processes, neural examinations should be informed by theoretical insights as well as thorough behavioral examinations (Krakauer et al. 2017).

A similar concern is seen in the refocusing of the goals of linguistic theory through the emerging biolinguistic program (Boeckx and Martins 2016; Chomsky 2007; Crain et al. 2017; Piattelli-Palmarini 2013; Piattelli-Palmarini and Uriagereka 2004, 2008). In a series of much-debated publications, Hale, Reiss, and colleagues (Hale and Reiss 2000, 2008; Isac and Reiss 2013; Reiss 2003, 2007) have argued for an *I-language* perspective, a speaker's implicit knowledge of her language, that which yields her observable utterances, is a system of computation that operates over symbolic variables. The rules of this computation constitute her knowledge of language, and a study of grammar constitutes an investigation of the shared properties of all such possible states of knowledge. Likewise, building on Reiss' arguments of modularity (Reiss 2007), Volenec and Reiss (2017) have proposed a framework for exploring the partial veridicality that holds between physical speech stimuli and mental representations of sounds and meaning. The authors argue that cognitive representation and processing of sounds of natural language are purely algebraic computations and that the primitives of such computations are independent of the stimuli that accompany their externalization. Similar arguments have also been made by cognitive scientists and psychologists exploring other types of information processing in the brain (Fodor and Pylyshyn 1988; Gallistel 2007; Gallistel 1981; Pylyshyn 1984; Marr 1982).

It is perhaps a sign that aforementioned developments have been able to bridge the gaps between the cognitive sciences and the more basic natural sciences, that in recent years there has been an increase in research activities focusing on the place of cognition within nature and the status of cognitive sciences as natural science. For instance, Medeiros and colleagues have reported that linguistic computations manifest putative universal patterns observed generally in nature (Carnie et al. 2005; Medeiros et al. 2016)

and that linguistic structures like the *x-bar* schema are results of optimal computations in a very general sense. Krivochen and Saddy (2018), likewise, report empirical evidence to support the same position. Further, Piattelli-Palmarini and colleagues (Piattelli-Palmarini and Vitiello 2017) have reported remarkable isomorphisms between various cognitive processes and field quantum theory, while seminal research in bioinformatics have recently reaffirmed the feasibility of classical computations on biological substrates (Green et al. 2017).

Conclusion

In the end, it remains a matter of perspectives whether or not the cognitive revolution was a single event localized to a single year in history, or a series of events over the years, and whether it had set for itself a fixed set of goals and agendas. What can be said definitively, however, is that a sort of Kuhnian paradigm shift has gradually come to pass and has exerted enormous influence across several disciplines (psychology, philosophy, neuroscience, linguistics, anthropology, etc.) and resulted in the prosperity of newer ones (artificial intelligence, cognitive science). It was marked by a shift in perspectives from observation of behavior and correlational stimulus-response behaviorism to more causally explanatory theories of cognition. It has not, however, been a uniform movement, having given rise to many contending frameworks (cf. Fodor and Piattelli-Palmarini 2011 and Hauser et al. 2002 vs. Pinker 1997 and Pinker and Jackendoff 2005; Prince and Smolensky 1993 vs. Hale and Reiss 2000), that nonetheless can be argued to share broad assumptions regarding the object of inquiry. As an intellectual movement, it was sparked by a break from a dominant paradigm, was inspired by newly emerging fields of research in computation, and has been fundamentally influential in refocusing several research questions even if it has not always provided conclusive answers. There are few conclusive ends in science, being that as a project, science is characterized by continually

evolving understandings of nature. However, to the extent that scientific inquiry is dependent on scrutiny and periodic readjustment of its methods and tools, the cognitivist phenomena have been nothing short of a revolution.

Definition

“Cognitive science” is an interdisciplinary field that focuses on the mental architecture of the mind and how it processes information, specifically how the brain functions with respect to emotion, attention and consciousness, language, perception, learning and memory, and executive functioning.

Introduction

The theoretical roots of cognitive science can be traced back to over 2,000 years ago. However, cognitive science as a formal discipline was established in the 1970s. Several “precursors” catalyzed the field of cognitive science being recognized as a legitimate field of study, namely, criticism toward behaviorism, computational and algorithmic mathematics, linguistic analysis, and models of information processing. Behaviorism contributed to our understanding of problem-solving (Tolman and Honzik 1930), learning (Tolman et al. 1946), and higher-order behaviors (Lashley 1951). Computational and algorithmic mathematics contributed to our understanding that the mind does not operate in a strictly mechanistic manner. Rather, the mind makes use of an *algorithm* to be used in a systematic manner across an array of situations and domains (Turing 1936, 1950). Linguistics taught

us that language also makes use of complex algorithms, specifically the ability to transform or convert sets of symbols into different strings of symbols (Chomsky 1957). Models of information processing demonstrated that the human mind tends to “bottleneck” in regard to how much information can be efficiently encoded, stored, and retrieved (Miller 1956). Lastly, the ability of one’s mind to function in such a systematic and complex manner is a product of how the brain has evolved over time; some processes are selectively reduced or eliminated, whereas others may be emphasized and preferentially expressed.

Components of Cognitive Functioning

Cognition can be conceptualized as a dynamic and interrelated set of functions that encompasses perception, emotion, executive functioning, learning and memory, language, and attention and consciousness. *Perception* refers to a person’s ability to detect the presence of a stimulus (novel or habitual). The process of perception can be conceptualized as a person’s ability to believe that “something” is a “certain way” based on set parameters or expectations (i.e., representational theory; Harman 1990; Loar 2002). In other words, perception is a modular approach to processing sensory-related information that is mediated by specific sensory-related algorithms (Fodor 1985; Marr and Nishihara 1978; Pylyshyn and Turnbull 1986). *Emotion* can both influence and be influenced by cognition. For example, one’s “appraisal” of a situation will facilitate a process, whereby the person evaluates its environment in relation to its goals and/or well-being, thus eliciting some type of emotional response to contend with the situation (e.g., depression; Arnold 1960; Lazarus 1991). Conversely, a person who experiences chronic depression may view future situations or interactions in a negativistic manner, thereby perpetuating a depressionogenic “schema.”

Executive functioning is comprised of several cognitive processes that allow a person to reason, problem-solve, make decisions, and engage in a goal-directed behavior. For example, reasoning

tends to be associated with how a person makes use of new information; mental representations of conditions can be modified as a result of previous knowledge (i.e., “semantic/pragmatic modulation”; see Johnson-Laird and Byrne 2002). Alternatively, decision-making focuses on how a person’s beliefs and values direct their choices; “prospect theory” asserts that in a value function situation, people tend to take risks when it is framed in terms of loss. Conversely, people tend to avoid risk when it is framed as a gain (Kahneman 1979).

Current theories of *learning and memory* assert that there are three types of memory: working, short-term, and long-term. Working memory describes a process where information is temporarily held to be manipulated in order to perform a task (e.g., seconds), which may later be transferred into short-term and ultimately into long-term memory (Miller 1956). The multicomponent theory of working memory by Baddeley and Hitch (1974) states that a stimulus registers on a sense organ and then transfers within several “subsystems,” the phonological loop, episodic buffer, and visuospatial scratchpad, all of which are mediated by the central executive. Conversely, short-term memory describes a process where information is temporarily retained over a period of brief delays (e.g., seconds to minutes; Murdock 1974). Alternatively, long-term memory describes a process where information is stored over a long period of time (Atkinson and Shiffrin 1968; Murdock 1974). Moreover, the process of memory involves four steps, initial encoding, storage, forgetting, and retrieval, although contemporary theories also include consolidation and reconsolidation as two additional processes, especially as the latter two facilitate long-term memory (Craig and Lockhart 1972; Ebbinghaus 2013; Müller and Pilzecker 1900).

Cognitive science has used the analogy of computers as a means to define how the human brain processes information or communicates within itself. With that analogy in mind, the primary method of communication within a computer is a binary or symbolic system of *language*. Language processing emerged from the physical symbol hypothesis, which states that

intelligent life transforms physical symbols as to act on it in some meaningful way (Simon and Newell 1975). This hypothesis was expanded upon by Fodor, who created the language of thought hypothesis, which states that basic symbols are stored in the mind. However, information processing is facilitated by transforming symbols into sentences and language of thought (Fodor 1985, 1987).

Attention and *consciousness* are interdependent cognitive processes; attention refers to one's ability to orient one's senses (e.g., visual, tactile, olfactory, auditory) to perceive and encode a stimulus. Types of attention include simple, focused, sustained, divided, and rapid alternating. Alternatively, consciousness refers to a person's awareness or ability to react to stimulation in the environment (Wolman 1989). Consciousness also refers to one's level of arousal and varies along a continuum ranging from coma, stupor, delirium, and normal consciousness (Inouye et al. 1990; Levin et al. 1979; Lipowski 1990). Both processes are integral in a person's ability to detect sound, position, shape, color, texture, and temperature of stimuli. Two state consciousness-based theories have shaped how consciousness is conceptualized: the higher-order perception (HOP) and higher-order thought (HOT) theories (Armstrong 1968, 1981; Bayne and Chalmers 2003; Dainton 2000; Lycan 1987, 1996). The HOP theory asserts that consciousness is achieved via higher-order representations of a stimulus, with internal monitoring/introspection of one's own mental/brain states. Alternatively, the HOT theory asserts that consciousness is achieved by simply having a thought, essentially removing the necessity for introspection or monitoring of brain states.

Collectively, cognitive functions such as emotion, attention and consciousness, language, perception, learning and memory, and executive functioning have served an evolutionary purpose. Over time, *Homo sapiens*' ability to attend to, perceive, and determine a course of attention (i.e., executive functioning) has evolved from experiencing threatening predators to experiencing the nuances of complex work environments. In either scenario, both pertain to the vital

longevity and security of the organism (e.g., staying alive vs. staying employed). Emotions have provided *Homo sapiens* the qualitative product of cognitive functioning. For example, emotions may be functional, whereby information is processed and acted on for a specific utility (e.g., jealousy as a means to alter a threatening relationship), and emotions may be constructive, whereby information provides the organism cues to the survival-related nature of a situation. *Homo sapiens*' ability to learn and remember information transcends human evolution as a means to remember past experiences and adapt them to relevant situations for optimal survival and prosperity. Lastly, language has facilitated the *Homo sapiens*' ability to convey thoughts and ideas among his/her peers for optimal tribal or familial functioning.

Evolution of Cognitive Science

Cognitive science has much in common with psychology, especially its philosophical underpinnings attributed to Plato's *tripartite theory of the soul* where he considered one's "psyche/soul" the essence of a person and that a person's psyche is composed of *logos* (the mind), *thymos* (emotion), and *eros* (desire). Moreover, Plato's *Meno* posited that humans are born with innate knowledge and that learning is a process, whereby a person seeks to recollect that knowledge (i.e., anamnesis). French philosopher René Descartes supported Plato's theory of multiple souls; however, he further asserted that the mind and body were separate entities, whereby the mind is non-physical and is responsible for consciousness and awareness (i.e., substance dualism), eventually leading to the present-day "mind-body" debate.

In contrast to Plato and Descartes, British philosopher John Locke would assert in his *An Essay Concerning Human Understanding* that the mind is a "blank slate" at birth, without parameters for information processing, and that such parameters are later added to guide information processing based on one's unique sensory experiences throughout life. While rudimentary, Locke's theory supports present-day neurobiological

evidence that the brain is designed to process unique, sensory-related information as a result of cytoarchitectural differences within the brain. In 1819, physician T. I. M. Forster coined the term “phrenology,” referring to a pseudoscientific discipline based on Franz Joseph Gall’s accountings of brain functioning. Phrenology espoused that one’s intellectual or mental abilities were proportional to a given brain region and that each brain region created a unique shape within the cranium. Thus, one could infer a person’s relative mental strength or weakness based on the relative indentations within a person’s cranium.

As medicine and science observed the flaws within phrenology, notable pioneers such as Fechner, Weber, and Helmholtz laid the foundation of the field of “psychophysics” considering earlier philosopher’s accountings of mental activities. As such, German physician Wilhelm Wundt expanded the findings from Fechner, Weber, and Helmholtz and would become the “father of psychology,” creating the first laboratory of experimental psychology that examined aspects of brain-related functions such as perception and memory. Another notable discipline would contribute to the founding of cognitive science: behaviorism. Skinner’s radical behaviorism emphasized the necessity for strict observation of behaviors, since mental processes or introspection had no place in psychology. Skinner’s diligence and structuring of experiments laid the necessary groundwork from which cognitive science would later develop. Moreover, while behaviorism took root in the United States, Gestalt psychology and the concept of “schemas” emerged in part due to the contributions of Sir Frederic Bartlett (memory distortions), Jean Piaget (organized stable systems), Lev Vygotsky, and Alexander Luria (language and thought). The schema concept appealed in large part because it succinctly described how sensory-specific information is encoded, retained, and utilized in context-specific interactions, a concept that would later be expanded on by computational models and neural network theories.

The “cognitive revolution” was born in the 1950s as a means to distinguish itself from the

field of psychology. However, the actual term “cognitive science” was coined in 1973 by Christopher Longuet-Higgins in his “Lighthill report” (Longuet-Higgins 1973). Leading up to the revolution was the advent of cybernetics in the 1930s and 1940s, which described the organizing principles of the minds within humans, animals, and machines. The 1940s provided the *Theory of Computation* with the “Turing machine” being the most famous example of a basic computer (Turing 1937). Moreover, the advent of the modern digital computer, or “von Neumann architecture,” in 1945 formed the basis of theories associated with both human and machine-based operations; it was composed of a processing unit, a control unit, memory, external mass storage, and an input and output mechanism (Von Neumann 1993).

In the 1950s, the concept of “generative grammar” demonstrated that language is governed by a set of rules that generate combinations of words for specific functions. This concept laid the groundwork for computational models that espoused a “universal grammar” or syntax that allow both animals and machines to communicate both within and between each other. The 1970s and 1980s brought about the age of artificial intelligence (AI) with advancements in understanding how humans and machines communicate, problem solve, and make decisions. The 1980s and 1990s brought about the age of artificial neural network models, most notably James McClelland and David Rumelhart’s parallel distributed processing (PDP). The PDP approach asserted that information is encoded across multiple systems, where localized information is synthesized across multiple domains or systems and translated into a user-specific function or product (McClelland et al. 1986). At the same time, the field of neuroscience made significant contributions to cognitive science with the use of neuroimaging techniques with high spatial resolution, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). Both imaging techniques have allowed scientists to identify blood flow-related cerebral changes in the context of a specific task. Moreover, the use of electrophysiological techniques such as

electroencephalography (EEG) to measure event-related potentials (ERP) have allowed scientists to identify temporal-related changes in the brain while engaged in a specific task. In sum, neuroimaging and electrophysiological techniques continue to alter how we conceptualize the architecture and functions of the mind.

Encephalization and Cognitive Science

Encephalization refers to expected brain growth/size in relation to a mammal's body size and is measured by calculating the encephalization quotient (EQ) (Jerison and Barlow 1985; Kappelman 1996). Higher EQs are associated with greater brain volume and reliance on higher-order intelligence, whereas lower EQs are associated with lower brain volume and reliance on basic intelligence. *Homo sapiens'* brain reflects a much larger brain in contrast to its australopithecine predecessor, thus reflecting a higher EQ by comparison. With larger brain sizes, *Homo sapiens* possess greater cortical "real estate" and increased diversity in neuronal cytoarchitecture, allowing them to acquire high-order skills (Jerison and Barlow 1985). However, contemporary research emphasizes the analysis of specific brain regions to determine relative cognitive capacities (Barton and Harvey 2000; Shultz and Dunbar 2010).

From Hominid to Artificial Intelligence

Hominid is a phylogenetic term used to describe a tribe of primates, of which human beings are members. Hominid is also a term used to describe the relative adaptive changes that have occurred across species within the tribe as a result of changing ecological and selective conditions. *Homo sapiens'* brain has evolved with the advancement in technology, placing a greater demand on what would be required for optimal functioning in one's environment. Moreover, culture has greatly influenced how *Homo sapiens* behave, from influencing one's ability to communicate with others, making inferences of others'

intentions, and appraising situations (McBrearty and Brooks 2000). As a result, cerebral organization has adapted over time to accommodate changes in its architecture. Contemporary theories emphasize that architectural changes were a necessary evolution in *Homo sapiens* for efficient information processing abilities, which is best measured by one's *fluid* or *general intelligence* (*g* or *Gf*), a statistical outcome that describes one's "crystalized intelligence" in an effort to problem-solve (Cattell 1963).

One of the more prevailing theories in cognitive science emphasizes a *dynamical systems* approach in understanding how intelligent life functions. This approach asserts that a dynamical system is any system that evolves over time in a law-governed way; this includes human beings as well as machines (Thelen and Smith 1993). As *Homo sapiens* have evolved, our curiosity about what makes intelligent life "intelligent" has also evolved. The advent of AI has sought to uncover such mysteries by transposing neurobiological and philosophical accountings of cognitive functioning into a man-made system or machine. Moreover, cognitive scientists have evolved in their conceptualization of AI, viewing AI organization from the perspective of *agents of architecture* where information processing is determined by (1) a simple reflex, (2) a goal, or (3) learning to viewing it as a series of cognitive subsystems with domain-specific processes (i.e., modularity of mind; Fodor 1983; Russell and Norvig 2003, 2009).

Conclusion

The evolution of cognitive science is very much reflective of the zeitgeist. With the advent of neuroimaging in the 1950s, much of our understanding of the human brain has shifted or has been completely altered. Moreover, we know that culture and society have greatly impacted the cerebral architecture of *Homo sapiens'* brains; as such, our understanding of "cold" cognitions (i.e., information processing-based) and "hot" cognitions (i.e., emotional arousal-based) has altered our understanding of intelligence. Consequently, our

“evolution” on how we have conceptualized cognitive functioning and intelligence has also shaped how we harness such newfound information with its application to AI. Evolution is an ongoing process, and with it, so is our understanding of the human mind.

Definition

Mating interruption due to male’s copulatory organ withdrawal previous to a forthcoming ejaculation.

Introduction

Coitus interruptus is a widely diffused practice in humans and is considered the most ancient form of birth control method, being firstly described in the Genesis. Nowadays, there are different lines of thinking in whether considering onanism as a contraceptive method or not. The perception of its effectiveness seems to vary depending on the sociocultural context or the age of the practicans

(Sznitman et al. 2009; Gilliam and Hernandez 2007; Higgins et al. 2014), and a common agreement on its efficacy seems to lack also among academics. Some studies pointed out that conception may occur during copulation (i.e., mating) before ejaculation, due to the presence of sperm in the seminal fluid, or that onanism requires experience to be effectively practiced, meaning therefore that coitus interruptus does not represent a valuable and reliable contraceptive method (Doherty and Stuart 2011; Gilliam and Hernandez 2007; Lampiao 2014). By contrast, other studies proposed that onanism should instead be considered as an efficient method for birth control, since it remains one of the most widespread to prevent pregnancy (Lampiao 2014; Sznitman et al. 2009).

However, this last idea finds little support while the general tendency is to consider coitus interruptus as a poorly efficient practice, responsible for several cases of “side” pregnancies, reaching a peak of 27 % among women users within the first year of use (Doherty and Stuart 2011). Also, it is normally associated to scarce education environments, poverty, and lack of information or other contraceptives (Doherty and Stuart 2011; Sznitman et al. 2009).

Interestingly, onanism occurs in different forms also in other organisms than humans, meaning that this sexual behavior is not exclusively adopted by our species and that there might be room for a broader *evolutionary* consideration. This fact is remarkable as from a biological point of view, a trait displayed by a higher number of organisms allows a better understanding of the causes triggering it.

Onanism Types

Coitus interruptus does not occur only in humans. Even though onanism from an anthropocentric point of view is assumed to be a male voluntary act, if we abide by its definition we can ascertain its occurrence also among other species. For clarity, it is important to remark that *coitus interruptus* should not be confused with a generic *copulation interruption*, as it defines a different moment of

the sexual intercourse, namely instants before ejaculation. Indeed, while copulation interruptions are more likely to happen due to a variety of possible factors, as for instance predatory attacks, the greater majority of copulations in nature is meant to reproduce, resulting in a restricted number of species performing coitus interruptus.

We can distinguish between two different types of coitus interruptus, *voluntary* and *non-voluntary*. Voluntary onanism occurs when a male interrupts copulation on purpose or allows female to interrupt it before ejaculation and is diffused in humans and a few other primates, as for example, Sichuan snub-nosed monkeys (Li and Zhao 2007). In this monkeys males are polygynous (i.e., they mate with multiple females), and when copulation occurs the mating couple is often harassed by an extra-pair female. This fact induces males to leave the first female they are copulating with, to mount the heckler female to complete the sexual intercourse in more than 50 % of cases (Li and Zhao 2007). The heckler female harassment may consist in staring at the couple only, therefore male’s decision to stop mating with the first female before ejaculating is entirely voluntary, as there might be no physical contact between the couple and the heckler. In this study system, coitus interruptus is thus performed with the first female only, while sperm transfer occurs during copulation with the heckler female.

Nonvoluntary coitus interruptus is instead nondependent on male intentions. For instance, it has been reported for dogs, where it simply seems to happen accidentally: When a male is not successful in locking to mount a female, a so-called phantom lock may occur, consisting of the male remaining in the mating position and rhythmically releasing sperm, even if the female has moved away (Beach 1970). Another example involves meadow voles, but in this case sperm release outside female reproductive tract happens as a consequence of her decision not to be fertilized. Females during mating may run away just before male ejaculates, resulting in sperm wasting (delBarco-Trillo and Ferkin 2006).

Evolutionary Meaning of Onanism

Coitus interruptus is voluntarily performed in humans in order to avoid unintended pregnancies. This behavior is preferred in certain cases to other contraceptive methods, since the “dopaminergic reward” (i.e., the general feeling of pleasure and satisfaction related to the orgasm) is perceived to be higher and more gratifying (Gilliam and Hernandez 2007; Free and Alexander 1976). However, coitus interruptus functional usage may have deeper roots. If we analyze the meaning of coitus interruptus from a cost-benefits perspective, we can contextualize it more properly in a biological scenario. For example, in species providing broods parental care, it would be advantageous not to reproduce if resources are limited. This idea is reinforced by the fact that the only species adopting voluntary onanism also have strong parental care. Regarding humans, for example, from an ecological point of view what is considered as an opportune moment to have children in our society, namely having a good and safe working position and a stable relationship, could also be seen as a resource-predictable stable environment, in which the costs of reproduction (general metabolic effort, food supply, broods care, etc.) appear sustainable. If resources are limited instead, it might be advantageous to simply benefit from the “dopaminergic reward” for both sexes, avoiding conception. Benefits in improving social relationships and avoiding contrasts might also be involved. For instance, it has been shown in Tibetan macaques, another social primate, that nonreproductive matings improve couples synergy, increasing foraging together and proximity, and reduce conflicts among group members (Li et al. 2007). Voluntary onanism might also involve costs. If we think about human relationships, it is reasonable to assume that a greater majority of couples uses some forms of birth control practices, meaning that independently from the chosen method, the number of nonreproductive matings (meant to benefit from the “dopaminergic reward”) vastly overcomes the number of the reproductive ones. Since it has been shown in variety of species that there is a negative correlation between number of

matings (in term of ejaculations) and life expectancy, meaning that multiple copulations speed up the aging process, pregnancy-avoidance behaviors involving ejaculation, including coitus interruptus, might therefore be costly for males. From a female perspective, matings in general are associated to the risk of diseases and parasites transmission, thus if the number of matings increases due to the possibility to avoid the costs of pregnancy by using contraceptive methods, the risk of infections is also likely to be more severe.

While voluntary onanism is likely to involve both costs and benefits for the two sexes, if we consider nonvoluntary coitus interruptus under the same cost-benefits light we realize that for males it is likely to only involve costs. For instance, males might face sperm wasting, lost paternity opportunities, metabolic effort in sperm reproduction, and failure in mate acquisition. On the other hand, females might instead acquire benefits. In the case of meadow voles it has been proposed that the induced coitus interruptus may function as an honest signal for males quality, allowing them to assess whether they are mating with a good partner or not. Indeed, higher quality males should be able to monopolize females holding them to prevent escape attempts (delBarco-Trillo and Ferkin 2006), with the females receiving the benefit to conceive with a sure value male. By contrast, meadow voles males only seem to pay costs related to this female strategy, as they suffer for reduced number of ejaculations, meaning that males that experienced coitus interruptus might be more careful in mating due to previous negative events and/or that females discriminate these males (delBarco-Trillo and Ferkin 2006).

Anyhow, it is reasonable to suppose from an evolutionary point of view, that the sex promoting onanism occurrence is the one receiving general benefits from this behavior, favouring therefore selection for the trait.

Conclusion

At a first glance, coitus interruptus may only seem an “easy and quick” way to avoid unintended

pregnancies. A deeper consideration reveals that it is not only widespread in humans but is also present in other species. There are two different types of onanism, voluntary and nonvoluntary. Voluntary onanism is diffused in primates including humans and is meant to prevent conception with a particular partner or to obtain a “dopaminergic reward” avoiding the costs of pregnancy. Different pressures are instead acting on nonvoluntary coitus interruptus, ranging from conflict of interests between sexes to accidental events, and it occurs also in nonprimate mammals.

Independently from its real efficacy, coitus interruptus is perceived in humans as a valuable contraceptive method, remaining also nowadays one of the most used.

Color Red

Emily J. Bethell
Liverpool John Moores University, Liverpool,
UK

Synonyms

Badge; Sexual signal; Social signal; Status symbol

Definition

Red coloration is a highly salient visual signal caused by the light reflective properties of blood oxygen saturation in exposed skin and enhanced carotenoid levels in skin coverings. May be sexually or socially selected trait associated with enhanced reproductive success and dominance across a range of animals, including insects, birds, and mammals including humans.

Introduction

To the human eye, red stands out. It grabs attention. It signals romance... danger... stop! We

“paint the town red” when we celebrate and “see red” when we are angry. It is used widely in advertising and the media to attract the public increase product sales. In the animal kingdom, red coloration is evident across invertebrate and vertebrate species and, as in humans, may signal either a mating opportunity or danger (Osorio and Vorobyev 2008). The biological relevance of the color red has driven the evolution of trichromatic color vision (ability to distinguish red from blues and greens) in the visual systems of most anthropoid primates; argument remains about the extent to which this was driven by the adaptive benefits of better detecting ripe fruit, leaves, or sociosexual signals (Changizi et al. 2006; Osorio and Vorobyev 2008).

What Causes Red Color?

Red color in species with exposed skin (such as anthropoid primates) is caused by blood oxygen saturation and carotenoid levels, both of which reflect underlying physiology and signal health status (Changizi et al. 2006). The former indicates cardiovascular fitness and short-term emotion states such as anger or embarrassment, while carotenoids, which are pigments obtained from plants in the diet, indicate nutritional status. The property of “redness” emerges from the interplay between the biological characteristics of both a signaler and a receiver. A “receiver” must possess receptors and a visual system sensitive to wavelengths at the red end of the spectrum in order to detect the red color for it to become a “signal” (Elliot et al. 2015).

Red as a Sexually Selected Signal

Sexual dimorphism in secondary sexual characteristics containing red reveals a role of red in sexual selection, as originally proposed by Darwin. The evolution of red as a secondary sexual characteristic can be explained by Fisherian runaway selection: for example, a positive feedback mechanism involving female preference for red in males would result in increase in male red traits

and female preference for red in subsequent generations (Elliot et al. 2015).

Empirical evidence for red as a sexually selected trait comes from its association with enhanced reproductive success across a range of species. In humans, for example, when asked to manipulate pictures of faces to enhance healthy appearance, both men and women increase the red component of male and female faces (Stephen et al. 2009); women are more likely to wear red clothes during their fertile phase (Eisenbruch et al. 2015) and are rated as more sexually desirable by men than when they are dressed in other colors (Elliot et al. 2015); female rhesus macaques, *Macaca mulatta*, with redder faces have higher reproductive output and receive more attention and affiliative behaviors from conspecifics than paler females (Dubuc et al. 2014); male rhesus macaques undergo reddening of facial and anogenital skin when receptive females are present, for which females show a visual preference, and which is associated with enhanced male reproductive success independent of dominance rank (Dubuc et al. 2014). A similar relationship is seen in Darwin's ape, the brightly colored Mandrill, *Mandrillus sphinx* (Setchell et al. 2008). Color expression in primates has been linked to androgen (e.g., testosterone) levels, which act as an immunosuppressant (Setchell et al. 2008). Red color may therefore provide a reliable indicator of male immune strength and physical condition (Dubuc et al. 2014).

Red as a Socially Selected Signal

Red color may also be a socially selected trait that is associated with aggression and dominance across a range of species (Osorio and Vorobyev 2008). Red clothing is associated with an increased probability of winning in competitive sports, and men wearing red are rated as more aggressive and dominant than are men dressed in other colors (Wiedemann et al. 2015); men with redder skin are perceived as more dominant than men with paler skin (Wiedemann et al. 2015),

probably because skin reddens with dominance-related emotions such as anger and pales with non-dominant emotions such as fear (Changizi et al. 2006). It is no coincidence that red is almost universally accepted as the color to signal danger across cultures (Elliot et al. 2015).

Red skin also provides a salient and reliable signal of dominance and competitive ability across primates. Anthropoid primates in which males fight for access to females, such as the Mandrill and rhesus macaques, undergo testosterone-regulated reddening of facial and anogenital skin when receptive females are present (Setchell et al. 2008; Waite et al. 2003) which provides an honest signal to other males of current androgen status, dominance status, competitive ability, and willingness to engage in fights (Dubuc et al. 2014; Setchell et al. 2008).

Red in Context

To understand fully the biological significance of red coloration, we need to place color within individual and situational context. Red color is not a singular trait, but rather a potentially variable attention-capturing cue that maximizes the probability of the "signaler" gaining a receiver. In competitive contexts, therefore, red is most often perceived as a signal of aggression and dominance, signaling danger, and triggering avoidance behaviors in the receiver (Wiedemann et al. 2015). In affiliative contexts, red is associated with romance and attractiveness, signaling reward, and triggering approach behaviors in the receiver (Buechner et al. 2014; Waite et al. 2003). In laboratory computer tasks, a red distractor on the screen impairs performance on an ongoing task, and this effect is strongest for men, possibly due to the stronger sensitivity to dominance and avoidance signals in men (Elliot et al. 2015). An apparently evolutionarily old attention bias for red therefore draws attention toward red cues in the environment, enhancing the motivational message of the cue (threat or reward) and directing subsequent approach-avoidance response (Buechner et al. 2014).

Conclusion

From santa to satan, lipstick to warning signs, the color red is of great biological and cultural significance to humans. The evolutionary basis for our attention bias for the color red lies deep in our primate past. Pre-existing biases for detecting red afforded by the evolution of trichromacy in anthropoid primates, together with the reliable signal value of red for reproductive status, dominance, and aggression, would have afforded a fitness advantage to individuals able to better detect fertile mates and respond quickly to avoid aggressive individuals in the ancestral social environment. The saliency of the color red to the human visual system is further supported by its widespread use in coloration of artifacts across human cultures and symbolism for heightened emotional contexts ranging from danger to romance.

Combat Sport

Garry Chick

Department of Recreation, Park, and Tourism
Management, Pennsylvania State University,
University Park, PA, USA

Synonyms

Combative sport; Contact sport; Fighting sport

Definition

A combat sport is a competitive activity engaged in by two individuals or teams that models actual combat wherein winning or losing is defined by agreed-upon rules and is substantially determined by physical contact and/or the use of real or simulated weapons by opponents.

Introduction

Play fighting is common among mammals, many birds, and members of some other taxa. It involves not only competition but also cooperation in that fighting is simulated but does not include injurious bites or blows or lethal bites as occurred in conspecific aggression or predation. Play fighting also involves play signaling and self-handicapping in one form or another. Among human children, play fighting is often referred to as “rough-and-tumble play” (RTP) which, when not suppressed by adults, involves approximately 10% of free play, particularly among males. RTP influences brain growth in rats, specifically in the number and complexity of cells in the prefrontal cortex, and animals deprived of play suffer from deficits in emotional regulation and social competence. Evidence from monkeys and apes is consistent with that from rats with the addendum that mother-child play is also critical. Among human children, positive play experiences with parents appear to enhance later peer-peer interactions. Children’s

RTP also seems to enhance social skills (Pellis and Pellis 2017).

Combat Sports in History

Wrestling is, in one form or another, the most widespread sport in human societies and probably a cultural universal. A wall painting at the Beni Hasan Tomb of the Egyptian official Baqet III (c. 2,000 BCE), for example, depicts wrestlers in a variety of positions, while *The Epic of Gilgamesh* (c. 2,100 BCE) describes a wrestling match between King Gilgamesh and Enkidu, a wild man created by the gods to challenge Gilgamesh because of his arrogance. The original Olympic Games lacked combat sports but added wrestling at the 18th Olympiad (708 BCE), boxing at the 23rd (688 BCE), and *pankration*, a sport somewhat similar to modern mixed martial arts, at the 33rd (648 BCE). In China, *jiao di* (“horn butting”) was a martial art dating to the third millennium BCE wherein contestants wore headgear adorned with horns and attempted to butt or throw opponents off raised platforms. It may have evolved into wrestling and other martial arts in China. Forms of grappling and wrestling were popular in Medieval Europe in addition to team activities known as “mob football” or “Shrovetide football” (Poliakoff 1995). Mob football is probably an ancestor of later forms of football but involved few rules and considerable violence.

Cross-Cultural Correlates of Combat Sport

In a 1973 publication, anthropologist Richard Sipes examined the absence/presence of what he termed “combative sports” among 10 extremely warlike and 10 largely peaceful societies in the anthropological record. For Sipes, combative sports are played by two opponents, either individuals or teams, and involve actual or potential body contact; may involve gaining playing field territory from the opponent, including the placing of a disputed object (often a ball) in a guarded location; or involve patently warlike activity. He

hypothesized that combative sports could either discharge innate aggressive urges among society members, rendering warfare less likely, or could be part of a culture pattern of aggressive behavior with warfare, therefore more common. Sipes found that warlike behavior and combative sports typically co-occur and that war tends to be rare where combative sports are absent. Chick et al. (1997) replicated Sipes' study with a larger sample ($n = 110$) and found modest for the culture pattern model. However, they uncovered much stronger support for the copresence of warfare and what they termed "sham combats," activities that are combative in that they may involve physical contact and, frequently, the use of real or simulated weapons. Unlike the usual case in sports, they typically lack winners and losers and rules for determining them. An unpublished replication using a 130-society sample with a multiple regression-based statistical method that accounts for missing data and Galton's problem, the possibility that two or more societies may have similar cultural traits due to a common history, diffusion, or both, does not support a relationship between the frequency of warfare societies and the presence of individual combative sports. The level of social and technological complexity of societies, but not the frequency of warfare, predicts the presence of team combat sports. The presence of sham combats, however, is strongly influenced by the frequency of warfare. These results do not support Sipes' (1973) claim that combative sports co-occur with frequent warfare, possibly because of the bivariate nature of his analysis, because of his inclusion of sham combats as combat sports, and because his data were composed of outliers.

Combat Sports and Gender

The appearance of female gladiators coincided with the rise in the popularity of the games during the late Republican era and reign of the first Roman Emperor, Augustus (i.e., 147 BCE – 14 AD) (Poliakoff 1995). However, participation in combat sports by females appears to have been rare, at least until recent years. In a cross-cultural sample of 50 societies, Deaner and Smith (2012)

found that 37 had combat sports. Males were the exclusive participants in 55 different combat sports, while none were exclusive to females. Both males and females participated in 2.

Female participation in modern combat sports, including wrestling, boxing, and martial arts, as well as team sports, including rugby and American football, has had periods of popularity. Competitive female boxing was first sanctioned at the Olympic Games in 2012, and the World Boxing Association created a unified women's boxing title in 2015. In recent years, however, professional women's boxing has been largely displaced by women's mixed martial arts. Several amateur women's American football leagues exist in the United States and elsewhere, but they have struggled to attract fans.

Combat Sport and Mate Choice

De Block and Dewitte (2009) viewed sports, at least in part, as culturally evolved signaling systems that function similar to courtship rituals in nonhuman animals. Thus, sports evolved, to some extent, via sexual selection. For De Block and Dewitte (2009), in order for sports to indicate fitness, they must, first, be informative with respect to qualities that are evolutionarily relevant. Second, they must be accurate in providing that information. That is, rules should ensure the highest positive correlation between a competitor's fitness and the likelihood that he or she will win. Third, the signal provided by winning should be transparent to possible recipients. As success in sport, especially combat sport, exhibits qualities, such as dominance and fighting prowess, which should be of interest to females, it should be important for males to demonstrate these abilities. Because it is rule-bound and standardized, sport offers a context that minimizes cheating as it is informative, accurate, and transparent.

Graves (2010) found that the average age of men who achieved championship status in international boxing, based on data from the World Boxing Association, was 26.44 years, while the mean age at which titles were lost was 28.35, suggesting that males reach their peak ability in this form of combat sport in their mid- to late

twenties and that this peak period lasts for just under 2 years. Graves (2010) noted that this is approximately the age where males have the highest reproductive success. Brewer and Howarth (2012) found that a sample of heterosexual women, aged 19–39, rated males depicted in photographs and described as “playing competitive sport aggressively” as more attractive and desirable for a date, relationship, marriage, and parenthood than when described as “playing sport on a casual basis.” The men were judged least attractive when described as “not playing sport.” Similarly, Lombardo (2012) hypothesized that sport originated as a context for men to develop skills needed in hunting and warfare and then display them to possible allies and rivals. In turn, champion athletes, particularly in combat sports, are accorded fame, status, wealth, and power, qualities that are attractive to women. Several empirical studies report that women are attracted to athletes, particularly those who play team sports, and that athletes have more sexual partners as well as greater reproductive success than nonathletes.

Deaner and Smith (2012) disputed the claim that sports serve as culturally invented courtship rituals, however, pointing out that females primarily advertise physical attractiveness and personal integrity when seeking mates, neither of which are particularly emphasized in sport. Moreover, to the extent that physical attractiveness, high status, and dominance are associated with sports participation, they accrue to males but not females (Brewer and Howarth 2012). Sports that involved judged display (e.g., gymnastics, figure skating) emphasize physical attractiveness but do not involve direct competition, let alone a combative component. Deaner and Smith (2012) attributed greater sports participation in males to several factors, including socialization, but also greater exposure to androgens prior to birth. The latter, if confirmed, would support evolutionary models that emphasize male-male competition in sport, including combat sport.

Modern Combat Sports

While many combat sports, such as wrestling, boxing, and other individual martial arts, are

ancient in origin, both individual and team events, such as jousting and the melee, were popular components of Medieval tournaments. Individual combat sports in the modern Olympics include boxing, judo, taekwondo, Greco-Roman and free-style wrestling, and fencing. Modern mixed martial arts (MMA), a combination of Brazilian jiu-jitsu and shoot wrestling, was introduced in the United States in 1993 and has developed into several subvarieties, the best known of which is the Ultimate Fighting Championship. Modern technology has resulted in new forms of combat sport, such as paintball and laser tag, both of which can be played either outdoors or indoors and by individuals or teams according to a variety of rules specified prior to commencing the activity. American football and rugby, two team combat sports with the former descended, to some extent, from the latter, are played widely and at both amateur and professional levels.

Conclusion

Sport likely evolved from juvenile mammalian play, including that of human children, as it incorporates behaviors, such as capturing, escaping, and fighting, that mimic adult survival skills (Lombardo 2012). Combat sports appear to be institutionalized and rule-governed descendants of play fighting among animals as well as human children's RTP. Most model some form of actual combat. Although combat sports are not exclusive to males, men watch and participate in them in much greater numbers and frequency than women. This suggests that combat sports may, to some extent, signal information to females regarding the fitness of participants while, among males, serve as competitions for status and reliably communicate qualities, such as strength and bravery, that characterize effective hunters and warriors (Apostolou and Athanasiou 2016).

Commitment Skepticism

Ana M. Reinke and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Commitment skepticism refers to a person's apprehension about their current or potential mate's commitment to the relationship, specifically regarding parental investment (Pillsworth and Haselton 2006). It is possible that commitment skepticism is an adaptation because it evolved as a way to screen for a reliable, long-term partner. *Error Management Theory* (Haselton and Buss 2000) (see entry), a middle-level evolutionary theory, has been used to explain commitment skepticism.

Generally, *Error Management Theory* explains why, in circumstances where a decision or judgment has an unknown outcome, people are more prone to making a *false positive* error in judgment (believe X is true when X is not true, also known as a *Type I Error*) or making a *false negative* error (believe X is not true when X is true, also known as a *Type II Error*). This theoretical model suggests that a tendency to make false positives or false negatives may have evolved if one error increased fitness benefits or minimized fitness costs. As an example, when detecting snakes, people are more prone to mistaking sticks as snakes (false positive) than mistaking snakes as

sticks (false negative) because the false negative would have been quite costly whereas the false positive would not. Applying this theoretical model to judging the intentions of a potential long-term mating partner, people can be wrong in one of two ways: believe the person will commit to the relationship when the person would not (i.e., false positive) or believe the person will not commit when the person would (i.e., false negative). In order to predict which type of error people are more or less prone to making, we need to consider both the net costs and benefits of either decision.

Choosing a mating partner is a rather important decision because it impacts the amount and quality of resources one gets for their offspring, so there may be particular costs to making the wrong decision about a potential mating partner. Because men and women differ on the costs and benefits of false positives and false negatives when predicting a potential partner's commitment, we also expect men and women to differ on the degree to which they show commitment skepticism.

Since women's reproductive success is strongly impacted by the quality and amount of parental investment from one's mate, the costs of choosing a partner who does not invest in offspring is much greater than the cost of losing a potential partner who would have invested. Since men's reproductive success is strongly impacted by mate number, the costs of selecting a partner who does not invest are not as steep if he continues to pursue additional short-term mateships. Under these circumstances, we would expect women to show a stronger tendency toward commitment skepticism (see *Sex Differences in Commitment Skepticism Bias* entry). Indeed, available data has shown that women are more prone to commitment skepticism than are men (e.g., Brown and Olkhov 2015; Haselton and Buss 2000), which is also consistent with theory and research that indicate women are "choosier" than men when selecting a mate.

Much more empirical and theoretical work is needed to fully understand the psychology of commitment skepticism. Some, for example, have challenged the pervasiveness of sex

differences in commitment skepticism and proposed alternative ways to consider the circumstances under which men and women show commitment skepticism (Al-Shawaf 2016; Brown and Olkhov 2015).

Definition

Watershed skills that human children develop early in life.

Introduction

Even before birth, children are making sense of the sounds they hear. The human ear is functional in the final trimester, and fetuses respond to a range of auditory stimuli from outside the womb. Evidence suggests that infants are in fact highly sensitive to the sounds they hear from within the womb and newborns can identify sounds from the language to which they have already been exposed while in the womb (May et al. 2011). De Casper and Spence (1986) asked pregnant women to read a short passage of text

aloud daily for the last 6 weeks of their pregnancy. At just a few days old, the newborn infants actively sought to hear the speech passage they had heard prenatally, rather than a novel passage. A control group of infants who had not been regularly read to during pregnancy showed no preference for either passage. Taken together, these findings suggest that language learning begins very early in human development.

Postnatally, infants continue processing the sights and sounds they encounter, showing a keen interest in faces and voices, as part of the social development which underpins later language learning. Infants only a few days old show a preference for looking at faces over other objects, and even newborns will orient toward the sound of a voice (Brazelton 1978), thereby providing the sensory information required to build the communication skills we see later in life. Although some researchers have dismissed early infant smiles as purely reflexive behaviours, there is evidence that, although rarer, smiles from newborns and very young infants do reflect early social engagement with caregivers (e.g., Oster 2005). Ultimately, the acquisition of typical communication skills requires the ability to both understand and produce both language and gesture. Here we consider the development of language comprehension, language production, and gesture and outline some key developmental milestones.

Language Comprehension

Every word starts out as a new word, so infants face enormous challenges in order to start decoding their own language (or languages). One of the first challenges for infants is to identify words from a stream of speech. Written language helps readers identify individual words by providing space between words, but this rarely happens in speech. In speech, words run into each other, and speakers often change the sounds of beginnings and ends of words to blend them with others (Ladefoged 2006). This makes identifying individual words particularly challenging.

Fortunately, infants can use a number of strategies to help them segment words from the speech stream. Cues such as prosody (e.g., the use of stress or rhythm in speech), intonation (e.g., changes in pitch), and even facial expressions (e.g., Mitchel and Weiss 2013) can support successful speech segmentation, suggesting that infants benefit from language exposure very early in development. Saffran et al. (1996) demonstrated that 8-month-old children could learn the statistical regularities of a nonsense language from as little as 2 min of exposure, even without any additional prosodic cues. This suggests infants can successfully integrate a range of cues, detecting those sounds which commonly occur together, and those which do not, to make judgments about where words begin and end, thus segmenting words from a stream of continuous speech.

Once a child has successfully identified a word, they need to attach some meaning to it. When hearing a word for the first time, children face the challenge of identifying its referent. A new word may have endless potential meanings; it may refer to an object, or any property of that object, a feeling, a time, or an action (Quine 1960). This *referential ambiguity* poses a challenge for the child, which they appear to solve rather effectively using a number of strategies.

The relative speed with which children appear to process the information required to map a new word to its meaning led to the coining of the term fast mapping (Carey and Bartlett 1978). Subsequent research, however, found this initial mapping to be rather fragile and suggests robust word learning takes place over time (Horst and Samuelson 2008). Markman (1990) suggested certain constraints guide young children through the mapping process. The *whole-object assumption* suggests that children interpret new words as labels for whole objects, rather than parts or other properties of objects. The *taxonomic assumption* suggests children extend words to taxonomically related objects rather than perceptually similar or thematically similar objects. Finally, *mutual exclusivity* refers to the way in which children map a novel word to a novel object, rather than an object for which they already know a label

(although children learning more than one language behave differently).

During early childhood in particular, caregivers typically support children's language development by adopting certain helpful styles of interaction. For example, adults typically speak to infants and young children using shorter sentences, repetition, slower speech, higher pitch, and hyperarticulation. This is referred to as infant- or child-directed speech, or motherese. Although cross-cultural research has found evidence of some cultural variation in infant-directed speech, the use of such supported speech toward infants appears widespread (for a review, see Saint-Georges et al. 2013). In addition to supporting children's language acquisition by adopting helpful speech styles, caregivers and other adults also use other means. Simple techniques such as use of ostensive naming can be helpful for word learning, but more simply, if caregivers wish to support language acquisition, they should provide the richest possible linguistic environment for their children. Children who are exposed to the widest range and volume of vocabulary are those who start school with the largest vocabularies. This means speaking directly to children or even exposing children indirectly to speech and reading to children are important activities. Infant-directed speech and storybook reading and talking to children all support emotional, social, and cognitive development, in particular, that of language comprehension and production.

Language Production

Language comprehension involves children processing what they see and hear and beginning to integrate this into their understanding of human behavior and communication. Children's language production typically lags behind their language comprehension. For example, children understand their first word long before they can produce their first word. Although language comprehension precedes production, infants begin to vocalize very early in life. Such vocal communication is shaped over infancy and childhood by many factors, not least those of experience,

motivation, and the development of the human child’s vocal anatomy.

The infant vocal tract is, of course, smaller than that of an adult but also proportionally shorter, due to higher placement of the larynx. A shorter pharyngeal cavity also leaves less room for tongue movement, and a lack of muscle control limits complex tongue movement. Anatomical differences between adult and infant vocal apparatus mean that certain sounds, for example, adult vowel sounds, rely on physical developments to take place before they can be performed (for a summary, see Vihman 1996).

Researchers have mapped children’s pre-linguistic sounds over development to provide a clear picture of children’s vocal development (e.g., Nathani et al. 2006; Oller 1980; see Table 1). Early production comprises reflexive or

involuntary sounds, such as crying, grunting, or fussing in a stage called phonation. Caregivers reward infants’ early cries with nutrition and comfort, and in the months that follow, despite a lack of vocal control, infants respond to adult vocalizations with vocal outbursts. In the months that follow, infants begin to have increasing motor control, enabling them to begin to experiment with the sounds they can produce. Infants produce cooing sounds and their first laughter at around 2–4 months of age. This is followed by vocal play or expansion, such as changes in pitch and volume, including long vowel sounds, until at around 6 or 7 months, infants begin to produce babbling sounds. Early babbling sounds include combinations of repeated consonant-vowel sounds (e.g., CV; \ma\ma\ or \ba\ba\) in what is termed canonical babbling. This is followed by variegated

babbling which includes a variety of consonant and vowel combinations (e.g., CV, VC, VCV; \ga \, \um\, \aba\), and at this stage infants vocal production begins to sound much more like adult language. Although there can be a great deal of variation in these linguistic milestones, children typically produce their first word at or around their first birthday.

Having mastered their first word, other single words follow. These first few words are likely to include words for family members, food, body parts, and other familiar objects or descriptive words such as “gone” or “dirty” as well as onomatopoeic words such as “woof” or “moo.” Early word acquisitions are likely to be single syllable and formed of simpler to produce sounds that do not require multiple consonant sound combinations, or more challenging pronunciations may result in some simplification (e.g., spaghetti might become a-ghetti). The pace of new word acquisition accelerates quickly during a child’s 2nd year, often termed the “vocabulary explosion,” even though most experts now agree this is a smoother and more gradual transition than the stage-like process described previously (Ganger and Brent 2004). Early accounts suggested children learn as many as ten new words per day (Bloom and Markson 1998) and marked a particular stage in development. More recent evidence points to more moderate gains of no more than two words per day for the 2nd year of life (e.g., Anglin 1993) and suggests more cumulative and generalized mechanisms may explain the exponential vocabulary acquisition (McMurray 2007) in the 2nd year of life.

Toward their second birthday, children have enough words in their vocabulary to combine two words, often a noun and a verb, enabling much richer communication. Then, shortly after, children begin to combine three or more words to produce telegraphic sentences. Telegraphic speech usually includes nouns, verbs, and adjectives but typically lacks articles, such as “the” or “a,” or prepositions such as “in” or “on.” At this point, children begin to demonstrate their knowledge of syntax (sentence structure) in the language they produce.

Competent language use requires more than just knowing words. Grammar plays an important structural role in language by providing a set of rules, which help impart meaning. Such structure can include syntax and morphology. Syntax describes change at the level of the sentence, so can be described as the order in which words are organized in a sentence. In English, for example, in a sentence such as “Ben pushed Jane,” the word order implies who carries out the action and who is the subject of the action. If the word order changes to “Jane pushed Ben,” this changes the meaning. Morphology describes changes at the level of the word. This includes, for example, changes to a noun to denote a plural by adding “s” or “es” or the addition of small units of meaning such as suffixes or prefixes to add meaning as in the case of adding “re” at the beginning of a word to mean “to do again.”

The most influential theoretical account for the origin of human language claimed that children have an innate, specialized ability to learn language. Chomsky (e.g., 1965) argued that children are born with a universal grammar, which sets out the possible “rules” for any language, and relied on language specific human evolutionary adaptations. Research examining many languages failed to find the consistency across languages needed to support Chomsky’s original claims. This led to subsequent modifications of the theory. A more recent alternative theoretical account is that of usage-based linguistics (for a review, see Ibbotson and Tomasello 2016). Usage-based theory suggests that language learning recruits more generalized brain systems and builds up knowledge of language from repeated exposure to it. This contemporary theory for language acquisition appears to better allow for the huge cultural variation in language and language development.

Gesture

Over the course of the 1st year of life, children begin to use gestures toward particular ends. Most readers will be familiar with the “reach up” gesture, in which babies raise both arms in apparent

requests to be picked up. Children adopt numerous culture-specific gestures that have conventional meanings within their cultures, but are not universal in meaning across cultures. Examples include waving bye-bye, sticking out one's tongue (a pejorative in some cultures, but a greeting in others), and various manners of pointing (Kirch 1979).

By the end of the 1st year of life, in Western cultures, babies can follow others' pointing gestures to close-by objects and, as they enter their 2nd year, to increasingly more distant entities (Adamson and MacArthur 1995). Usually within a few weeks of producing their first words, babies also start pointing, themselves. By the early part of their 2nd years, babies start to point to entities while simultaneously looking toward their social partners, thus displaying a parallel gestural/attentional deployment tactic that is often termed, "nonverbal reference" (e.g., Bates et al. 1975; Pechmann and Deutsch 1982). The developmental onset of pointing comprehension and production is the focus of considerable theoretical debate about the relationship between pointing and other nonverbal referential behaviors and the evolution of language. For many theorists, pointing permits states of psychological engagement unparalleled in the animal kingdom (e.g., Carpenter and Call 2013; Tomasello et al. 2007). According to this theoretical perspective, pointing signifies a human unique quality of psychological understanding between two people – (a) an appreciation that another has an independent visual perspective on the world that can be manipulated with pointing gestures, (b) that this visual perspective informs their understanding of the world, and (c) that this joint attention to some distal entity constitutes a shared psychological state of knowing together (e.g., Carpenter and Call 2013). As such, this capability for joint attention heralds a nonverbal mechanism for reference that is said to form a psychological foundation for the kinds of shared understandings of words (or symbolic reference) that occur with speech. One line of evidence for a supportive role of gesture in speech development is the finding by Goldin-Meadow and Butcher (2003) of increasing integration of gestures with speech over the 2nd and 3rd years of life: children

begin conveying different information in gesture and in speech, but eventually learn to convey two distinct topics in speech alone, and this is consistent with observations that children become less reliant on gestures as their speech skills improve throughout childhood (Pechmann and Deutsch 1982). For these and other reasons, some theorists have suggested that these gesture-initiated states of joint attention represent a biological adaptation that fosters language development uniquely in our own species. Consistent with this view, until fairly recently, it was widely believed that pointing with the index finger was both universal among humans and unique to humans among primates (e.g., Butterworth 2003; Povinelli et al. 2003).

However, now it is well-known that (a) pointing varies in its posture across cultures (Wilkins 2003) and (b) great apes (chimpanzees, bonobos, gorillas, and orangutans) readily adopt pointing gestures when they are raised in captivity (Leavens and Racine 2009). Rather than signaling uniquely human evolutionary cognitive adaptations, it may well be that pointing is a developmental response to linguistic communication environments in which much of social engagement is object-centered – about things – and that pointing reflects cognitive adaptations that are common to humans and their nearest living relatives, the great apes, when exposed to reference-rich environments. Evidence in support of this view is the observation that of the apes that have been raised like human children, in peoples' homes or as part of language-training projects, 100% of them display pointing, despite its extreme rarity among wild apes (Hobaiter et al. 2014; Leavens and Bard 2011). This evidence has supported the view of pointing gestures as a generalized hominoid (apes plus humans) response to the ecological effects of being raised in language- and artifact-dense environments. (A unique and subtle theoretical perspective on pointing has been developed by Juan-Carlos Gómez 2009: he argues that nonverbal reference and joint attention in humans rely initially on the same sorts of primitive cognitive mechanisms for understanding visual attention that we share with great apes but that a higher, representational capacity is eventually attained by humans, later in development.)

It seems likely that the ability to follow another's signals to focus on an object or location and the converse ability to direct another's attention (the two skills together are known as *joint attention*) assist babies in linking verbal labels with the objects of joint regard (Butterworth 2003). Many studies find that, for example, age at onset of pointing predicts later vocabulary size, as children develop (Colonnesi et al. 2010). From the standpoint of infants directing attention, they can elicit verbal labels for the entities that capture their interest. Conversely, from the standpoint of following directional cues, babies can use these cues to relate a visual object or activity to a verbal label.

Usually sometime after their first words, infants begin to adopt rich repertoires of conventional or symbolic gestures, such as waving “bye-bye” in some cultures (Acredolo and Goodwin 1988). During the 2nd year, children expand their expressive capacities by simultaneously using gestures with single-word utterances – this allows children to express more complex ideas than can be expressed in one word (Goldin-Meadow and Butcher 2003). As children's vocabularies begin to rapidly increase, usually near the end of the 1st year, and with their abilities to string successive words together, gestures tend to reduce in frequency with speaking, although of course we continue to gesture throughout our lives.

Conclusion

The developmental trajectories of language and gesture have been discussed separately here, but research suggests gesture and language are interdependent and jointly form human communicative interactions (e.g., McNeill 2003). This is the case both during the communicative interaction (e.g., gesture and speech are shaped by what we know about the communication partner) and over the course of development (e.g., early gestural use predicts subsequent language development). Traditional accounts of the development of communication in humans described such development as occurring in discrete stages, but more recent research

suggests children's acquisition of communication skills is much more fluid and features overlaps between the various milestones. It is therefore important to consider the inevitable individual variability that exists for each of the key milestones summarized in Table 1 during typical development.

Although we can now be relatively confident about the key milestones, which constitute early communication development, there remain many important unanswered questions. Understanding how humans acquire their distinctive communication skills, how and why these have evolved, and to what degree these reflect human unique skills are all issues that continue to prompt intense debate. Such questions make the topic of human communication development one of enormous importance when considering the place of humans in evolutionary history.

Definitions

Communication	the act of a message being sent by a communicator to a recipient; usually refers to aspects of spoken and nonverbal (e.g., facial expressions, gestures) language that enable message delivery and reception but may also refer to written language
Social cognition	mental processes that enable thinking about the self and others; key in navigating social situations and expectations

Introduction

Humans have evolved to communicate with one another through necessity and desire. After all, humans are social beings. In order to be successful group members, early humans communicated with one another within their social groups to coordinate efforts that promoted survival, such as hunting, gathering, and protection strategies. Communication was also used in early humans to warn of the approach of threats, such as predators. Later, written language developed throughout the world as a way to record historical events, important societal information, stories, and religious material.

Social cognitive skills such as perspective taking (i.e., theory of mind), empathy, pattern detection and recognition, interpretation of nonverbal and paralinguistic (e.g., tone of voice) signals, and others enable communication among individuals. One must be able to infer the intention of communication from others while also tracking in real time both the verbal and nonverbal signals being produced by the individual(s). Trust or mistrust for individuals may be garnered through communication. Indeed, such skills enable safe interaction among individuals, thus promoting survival. This, in addition to survival promoted within groups through shared language use, emphasizes the importance of the interconnectedness of communication and social cognition.

Aspects of Communication

Communication occurs when a message is conveyed through verbal, nonverbal, or other means from a message sender to a message recipient (Berlo 1960). Individuals communicating successfully with one another share a common ground regarding the topics of conversation, such that they are both relatively familiar with what is being discussed and are using a language or mix of languages that allow comprehension of information being exchanged (Clark 1996). Verbal communication contains linguistic and paralinguistic aspects, such as word choice and tone of voice, respectively (Prutting and Kirchner

1987). Another aspect of verbal communication is speech sound delivery. An additional paralinguistic characteristic may be an individual's typical volume of voice. Nonverbal aspects are the other major contributors to communication. These include gestures, facial expression, posture, and other body language. Indeed, some communication is carried out by solely using nonverbal signals (e.g., sign languages).

Verbal and nonverbal communication may be congruent or incongruent; that is, what a message sender is saying verbally may or may not match what their body language is portraying. For example, someone delivering a verbal apology may also wring their hands or show open hands or other common bodily signs of being regretful or sorry. The message recipient may perceive the message sender as genuinely apologetic, since these are nonverbal signals that one typically expresses when they are apologizing and asking for forgiveness. Conversely, the verbal apology may be paired with crossed arms and little eye contact, or even with aggressive body language, which would be incongruent with the expected sincerity of an apology. The results of incongruent verbal and nonverbal signals can vary (Morioka et al. 2016); the recipient may interpret the incongruence as insincerity (even if the verbal apology is present) due to the mismatch in what the person is saying and what their body language is portraying. Conversely, they may be put on alert as a result of the aggressive body language or gestures (effectively delivering the opposite of an intended apology).

Varying estimates have been postulated regarding how much information about a message is gleaned through verbal aspects compared to nonverbal and paralinguistic aspects. For example, Mehrabian and associates' (1967) historically well-cited work reflects a 55%/38%/7% breakdown of nonverbal, paralinguistic, and verbal aspects' contributions to communication, respectively. However, more recent research emphasizes various situational demands that may influence how a message is perceived (although nonverbal communication still tends to stick out as the major contributor). Thus, the manner in which a message is delivered is as important as the

message itself if one wishes to communicate effectively.

The way humans communicate and receive messages can signal prosocial or antisocial intentions to other individuals (Marzi et al. 2014). Consequently, communication can be viewed as a language-based way to test the safety or threat level of a person. An obvious example of a threat would entail an individual shouting and gesturing aggressively toward another person, which could engage the fight-or-flight response of the message recipient even if the verbal message was non-threatening. In fact, individuals identify "suspicious" nonverbal signals from others relatively quickly and easily, such as shifty eyes or nervous hand gestures. Research from the deception literature has demonstrated reliable effects of certain eye movements and microexpressions as signs of lying and deception (Matsumoto and Hwang 2018). Humans are able to quickly detect and process these types of signals, as they provide valuable information that may help determine whether the communicator is trustworthy, dangerous, etc.

Aspects of Social Cognition

Social cognition refers to the ability to think about oneself and others (Frith 2008). In particular, social cognition allows humans to function in social groups and societies through a shared understanding of social behavior and functioning. Much of what social cognition allows for is unconscious; that is, we automatically process many of the social cues that are presented to us in everyday life. For example, we automatically process facial expressions and the emotions they may portray. In many ways, this is how social cognition relates to human functioning and communication.

In the example of an individual attempting to deceive a conversation partner, nonverbal communication comprehension is seamlessly interwoven with social cognitive skills. Indeed, we create first impressions of people we are communicating with in a very short amount of time, and we tend to be quite accurate in our first

judgments about individuals (Ambady and Rosenthal 1993). Evolutionarily, this has been a survival skill when discerning intentions of others.

Social cognition is also involved in thinking about the self. Around 18 months of age, children begin to develop a sense of self-awareness and realize that they are an independent and different being from their caregivers and siblings (Brownell et al. 2007). They develop theory of mind by age 4–5, which allows them to know that not everyone possesses the same knowledge they do (Baron-Cohen 2001). Theory of mind also allows children to understand the emotional states and intentions of others, which are valuable skills for navigating social situations both early in life and throughout the lifespan.

While seemingly a skill relevant mainly to the self, theory of mind enables many aspects of communication. For example, knowledge of the self when communicating enables understanding of turn-taking and equal contribution with a conversation partner (Sacks et al. 1974). It also enables one to consider the feelings of another person when delivering difficult or sad news before communicating with them, allowing insight that can soften language. Here, empathy is also a central ability to communicative functioning. Therefore, knowledge of the self enables an individual to operate properly within the social realm.

Evolutionary Explanations for Social Communication

There has been much research into several specific effects of evolved social cognitive communication abilities in humans. The Chameleon Effect, for example, is housed under the skill set of nonconscious mimicry (Chartrand and Bargh 1999; Lakin et al. 2003). Nonconscious mimicry is a phenomenon in which an individual begins to mirror the verbal and nonverbal actions of another person, which creates positive feelings between the communicators. Indeed, the automatic processing of the mimicry on the part of the other

individual creates social bonding in that the individuals seem more similar to one another, signaling safety and belonging. The Chameleon Effect in particular is the human ability to utilize this skill set in social situations of many types in order to “blend in” with the nonverbal communication styles around oneself.

Another especially important instance of how social cognition and communication have evolved is the human ability to use context and inference to deduce meaning from a message (Lee and Harris 2013). In English, for example, homophones (i.e., words that sound the same but have different meanings and are spelled differently) such as “bear/bare” and “ate/eight” exist. In order to know which word is intended during spoken communication, one must utilize perspective taking and theory of mind to think about the context of the message that the communicator is attempting to create and then discern which word is being referenced. If a message about a camping trip is being communicated, the tendency is to interpret the homophone as the most relevant and likely word “bear.” This inferential ability is essential for gaining meaning from messages.

Another more organic example of how social cognition and communication have evolved is through the discovery of mirror systems in the brain. These systems are groups of neural networks that activate whether an individual performs an action or sees another person perform the action (Dickerson et al. 2017). For example, cooperation is an essential function in group maintenance and survival (Cosmides and Tooby 1992), and mirror systems allow for a platform of shared understanding when performing cooperative tasks and working toward a common goal. Moreover, mirror systems contribute to uniting factors such as empathy.

A final example of how social cognition and communication work together in an evolutionary sense is through the passing down of information, stories, and traditions with cultural themes (Kashima 2000, 2008). Historical information sharing and storytelling work to continue and strengthen cultural ties, enabling group

membership to increase in complexity as time passes. New generations of group members are told stories that may increase cultural understanding and dedication, thus increasing feelings of group belongingness.

Conclusion

The complexities of social cognition and communication enable some of the most essential functions of human bonding, group membership, and social belongingness. Neural network formation beginning early in life works bidirectionally in conjunction with automatic social information processing such as facial expressions and gestures, which continue to serve as the bases for social signal detection. Ultimately, efficient social cognitive skills facilitate communication, which can support such important factors as attraction, relationships, social belongingness, and group membership, thus increasing the likelihood of flourishing.

Definition

All animals communicate. Communication involves an action or characteristic of one individual that influences the behavior of another individual in a noncoercive way. One key way individuals communicate is through the use of signals. A signal is a display or act produced by a sender that influences the behavior of receiver, wherein the signal and its response evolved in senders and receivers because, on average, senders and receivers benefit from the use of the signal. Another key way individuals communicate is through the use of cues. A cue is phenotypic variation in a sender that causes a reaction in a receiver that benefits the receiver even though the phenotypic variation in the sender has not evolved to cause that reaction. This entry provides an introduction to these three topics, as well as a discussion of the evolution of signals from cues.

Introduction

All animals communicate. In fact, by many definitions of communication, all living things communicate (D'Ettore and Hughes 2008). Communication is perhaps the key organic body-to-organic body interaction that makes essential biological processes possible. These processes include everything from biochemical

changes on the surface of one cell that alter the metabolic activity of a nearby cell to the production of a mating signal by one individual that alters the likelihood of reproductive activity of a nearby individual. It is an inherently social act, and even the most solitary organism must rely on communication to achieve key biological ends, such as attracting a mate, warding off a competitor, or evading a predator that has detected it. Communication is therefore largely about changes induced in a receiver by a signal, and is one of the most fundamental biological processes observed in nature.

In the pages that follow, communication is first defined and described. Part of this discussion involves notions of information, manipulation, and management. These terms have become important in recent controversies over the use, and usefulness, of the term “information” in understanding communication in nonhuman animals (hereafter, animals). Following this discussion, signals and cues are in turn defined and described. As part of this discussion, the major kinds of signals, as well as the notion of signal reliability, are described. Many of the subsequent entries will go into greater detail on these issues, so the coverage here will be brief. Although the ubiquity of communication to biological processes in general was raised above, from here on out the discussion will be limited to animal communication.

Communication

In its broadest sense, communication involves an action or characteristic of one individual that influences the behavior of another individual. The first individual here is typically referenced with terms like sender, producer, signaler, or manager; the term “sender” will be used hereafter. The second individual here is typically classified as the receiver, target, audience, or assessor; the term “receiver” will be used hereafter. The action or characteristic of the sender is a signal or cue and not the direct exertion of the body of the sender on the body of the receiver. A large dog biting and attacking a smaller dog to the point of the smaller

dog running away is not communication, but rather a coercive action (Scott-Phillips and Kirby 2013). Conversely, a large dog growling and bearing its teeth to a smaller dog to the point of the smaller dog running away is communication. Whether growling and teeth baring in this example are communication through *signals* or *cues* of the sender is a topic addressed below.

The modality of communication is the means by which a sender produces and transmits its signals or cues. Visual, chemical, and acoustic modalities are the common modalities that most animals use (or at least the ones most heavily studied), although tactile, vibrational, and electrical communication is crucial for some species (Bradbury and Vehrencamp 2011). Visual communication includes permanent body shapes, colors, and markings; changes in posture, orientation, or movement of certain body parts; and alterations to the physical environment. Chemical communication includes lightweight volatile substances that can travel easily in air but tend not to last long in the environment, and also nonvolatile substances that are heavy in molecular weight and that typically cannot travel far but can remain on the substrate for long periods of time. Acoustic communication includes sounds produced inside the bodies of animals that are generated through specialized vocal production organs and projected outward from the mouth or head, and sounds produced on or outside the bodies of animals by either bringing two different body parts together or by one body part contacting the substrate. Although the discussion above implies or explicitly describes communication through the air, communication can also occur through the backgrounds of water or solid material such as plant tissue or the ground. The physical background through which these displays and communicative acts travel to receivers is the medium. The physical properties of the medium (e.g., how dense the vegetation is through which a signal or cue must travel) can select for different kinds of structure or patterning to the communication. Finally, for both the sender and receiver of the signals or cues, there are often specialized organs that have evolved in their particular species to make the communication effective and efficient. As just

two brief examples, consider the two sides of the syrinx and songbird species that allow for the independent production of distinct sounds, and the specialized external morphology of the outer ears of many terrestrial mammals that allow for flexible and directional capture of sounds in the environment. Even within a single communicative modality (let alone across modalities), there is enormous variation across species in sender production mechanisms, the signals and cues that are produced, and receiver perceptual mechanisms.

Although there is a tremendous amount of variation in how and why different species communicate, there are some overarching themes that all animals share. Perhaps the most obvious principle is that animal communication is essentially social. Without both a sender and attending receiver, communication is impossible (including in autocommunication, such as echolocation, wherein the sender is also the receiver of the signal). Communication furthermore makes other types of social behavior possible – from competitive interactions over access to a food resource to courtship interactions leading up to mating. Another general principle of animal communication can be found in Morton's "Motivational-Structural Rules" (Morton 1977). According to this view, birds and mammals that rely heavily on acoustic signaling tend to use harsh, low-frequency sounds when displaying aggression and they tend to use relatively pure, higher frequency sounds when frightened, appeasing, or approaching without hostility (Morton 1977). Perhaps there are parallels to these motivational-structure rules for vocal sounds in signal production in other modalities and in other taxa beyond birds and mammals.

For decades, communication has been defined as the exchange of information from a sender to a receiver that affects the behavior or physiology of the receiver. In his seminal text on communication, Smith (1977) describes the diversity of messages of nonhuman (and human) animal sender displays, and the potential meanings to receivers. The sender produces a behavior or possesses a physical trait that sends a message to receivers. In other words, the behavior or physical trait (often, a signal) provides information that

receivers can use in making decisions. The meaning of the communicative interaction is typically understood from the standpoint of the receiver collecting information about the environment – the signal or cue provides one portion of the information available to the receiver. The receiver gains meaning from the combination of the signal or cue itself and the context in which the signal or cue is experienced. Contextual factors include sender or receiver characteristics (such as current behavioral activity or state), sender *and* receiver characteristics (such as the nature and longevity of the relationship between the two individuals), or the environmental situation itself (such as the recent presence of a predator or competitor). In an important extension of Smith's ideas here, researchers need to consider not just the meaning that a receiver generates from the signal/cue and the context, but the decision-making process used by the receiver to choose its response to the signal/cue and the context (Fischer 2013).

A common approach to describe “information” and this decision-making process is to utilize statistical models. Signals and cues predict (in a probabilistic sense) events or states on the part of the sender that are important to the receiver. Receivers continually update their understanding of the world based upon their own previously acquired information, but also upon the information they glean from senders (e.g., from the signals produced by senders). Statistical decision theory involving Bayesian updating of information provides a recent and powerful approach used by researchers to generate predictions about communication's effect on receivers (Kight et al. 2013). Receivers pay attention to senders' signals and cues because they are associated with biologically meaningful variation in sender and environmental characteristics. This association with biologically meaningful sender and environmental variation is one of the key meanings of the term “information” for researchers studying communication.

Another key notion of information comes from the “Mathematical Theory of Communication” of Claude Shannon – information transmitted from a sender to a receiver reduces uncertainty in the receiver (Shannon and Weaver 1949).

Information here is “a measure of one's freedom of choice when one selects a message . . . in the simplest cases, to be measured by the logarithm of the number of available choices” (p. 9). One important component of this general view of information is that information relates to diversity. The greater the variation in the number and type of signals and cues available to a sender and receiver in a communicative interaction, the more information resides in that communicative system. In short, in two comparable species, the species with the larger repertoire of signals and cues is the species with more information that can potentially be communicated.

The previous few paragraphs have revolved around the idea of communication as the transmission of information from senders to receivers. This notion of information in communication has been criticized for various reasons for nearly 50 years (Burghardt 1970; Rendall et al. 2009). One of the major criticisms of the use of information in the field of animal communication is that it is a term that comes from writing and thinking about human language and human cognition (Shannon and Weaver 1949), and so carries a lot of unnecessary (and perhaps even harmful) theoretical baggage into the field of animal behavior. Perhaps the key criticism that stems from this argument is the notion of encoding that comes from Shannon's “Mathematical Theory of Communication” (Shannon and Weaver 1949). According to Shannon's view, a sender detects a stimulus/source of information in the environment and encodes that information into a signal, which then transmits through the noise of the environment to a receiver, who then decodes the information in the signal to determine what the stimulus/source of information was. The notion of information encoding by a sender suggests to these critics an individual consciously and with intent choosing signal *A* over signal *B*, to impart information to a receiver in a way that benefits both.

These critics argue that a stronger and more biologically valid way of viewing animal communication is in terms of senders influencing the behavior of receivers with the use of their signals through terms like manipulation and

management. Senders produce signals that are in their own best evolutionary interests to manipulate/manage the behavior of receivers, whether those signals benefit receivers or not. Senders do not encode information into signals, but, as described above regarding Smith's view (Smith 1977), receivers gather and assess information about senders from both their signals and from the context of the signaling. It is interesting that much of the terminology used by critics of the information view also brings with it significant cognitive baggage from human interactions (e.g., manipulation, management, propaganda, advertisement, assessment). This baggage can lead to a view of senders taking higher-order cognitive approaches to their behavior and strategically using their signals in sometimes deceptive ways to get receivers to act in ways that benefit senders. The anti-information view also seems unable to account for a good deal of interesting and important animal communication, including signaling sequences by two or more senders (McGregor 2005) and consistency in signal use over time by senders (Botero and de Kort 2013). Nonetheless, critics of views of information in animal communication have helped sharpen and strengthen ideas about signaling and communication, and have moved the field forward. A recent volume is the key summary of these arguments and is highly recommended as a starting point to the "information debate" (Stegmann 2013).

Signals

Signals are displays or acts produced by senders that influence the behavior of receivers, and do so because (a) they have evolved for that communicative function in senders, and (b) receivers' responses to those signals have also evolved, because, on average, senders and receivers benefit from the use of those signals (Maynard Smith and Harper 2003). If the use of a signal brings no benefit to senders in a given population, that signal will be selected against. Similarly, a signal that brings benefits to senders but costs to receivers in a given population should result in selection pressure for receivers to assess and discriminate

signals more carefully, to ignore or avoid such costly or unreliable signals.

With animals living in isolation, the signals they employ need not be complex. A short, periodic call may be sufficient to ward off territorial intrusion or to attract a mate. However, as organisms increasingly interact within complex social structures, components of the communication systems are also likely to increase in complexity. Many species are social – individuals in these species spend large parts of their lives in social groups, in close proximity and often engaging in repeated interactions with specific conspecifics (and perhaps heterospecifics) over time. Living in social groups brings benefits such as an enhanced ability to detect and respond to predators and food resources. These benefits of group living are often thought to accrue to prey species, but predators clearly benefit from sociality as well. For both predators and prey, the benefits of living in social groups often critically depend on information encoded in signals (Bradbury and Vehrencamp 2011; D'Ettorre and Hughes 2008).

In many animal species, effective and efficient social living requires social cognition. Social cognition can include a wide range of processes, such as the ability to recognize group members, remember past interactions, and strategically influence the behavior of others (Shettleworth 2010). Increased social cognition has been documented in species with more complex social groups compared to species with less complex social groups (Shultz and Dunbar 2007). Part of this increased social cognition likely includes effective and efficient signaling abilities. Without the ability to signal, sustained social interaction would be impossible and so signaling is crucial to the understanding of the evolution of social cognitive abilities. More complex groups often demand increased social cognition in group members; therefore, strong selection pressure is expected for enhanced signaling systems that provide individuals diverse behavioral ways to assess and manage the behavior of others in their groups (Freeberg et al. 2012). What are some of these major types of signals used in communicative interactions? A few of the major classes of signals are introduced here; readers should consult the

key reference on animal communication for the full range of signal types (e.g., Bradbury and Vehrencamp 2011).

Index Signals Some signals used by senders are directly related to their specific physical characteristics. These are called index signals, and cannot be faked by senders because the signals are so tightly constrained by earlier developmental conditions or by current physical state of the sender. For example, in the field cricket *Gryllus pennsylvanicus*, larger males produce louder calls at lower frequencies (Hz) compared to smaller males (Harrison et al. 2013). In these species, sound production stems from two body parts rubbing together, and the larger the body parts for a particular species, in general the more intense and lower the frequency of the sounds produced.

Handicap Signals Like index signals, handicap signals involve communicative acts and displays that are very difficult to fake, and so are typically reliable. These are signals that are effectively produced by individuals in good condition or of good quality and are costly to produce (Zahavi 1975). These costs can be borne easily enough by individuals of good condition/quality but are much harder for individuals of poor condition/quality to bear. For example, in males of *Anolis* lizard species, the rate at which push-up displays are produced is positively correlated with sender physiological condition, and increased rate of visual displays makes conspecific male intruders less likely to approach the signaling male (Brandt 2003). In these cases of handicap signals, senders in poorer condition can produce the signals, but only senders in good condition can produce the signals repeatedly at high rates – assessment of such signaling over periods of time will thus reliably indicate to a receiver the relative qualities of senders.

Conventional Signals Although definitions of conventional signals have varied over the years (and these changing definitions have caused confusion), a general view of this class of signals is that it refers to signals that are arbitrarily related to

the entity or condition with which they are associated (Guilford and Dawkins 1995). If signals are independent of associated entities or conditions (such as a level of arousal due to a detected predator or the body condition of a male signaling in a breeding context), they are relatively cost-free for senders to produce, or at least the costs of signal production are unrelated to variation in the entity or condition about which the communication is occurring. In these cases, senders might be expected to be less reliable in their communication. Several largely receiver-borne processes exist to ensure conventional signal reliability, however, including retaliation by receivers, alignment of interest between senders and receivers, and reciprocity or reputation (Bradbury and Vehrencamp 2011; Searcy and Nowicki 2005).

Referential Signals Referential signals are signals that are specifically associated with certain stimuli in the environment (Bradbury and Vehrencamp 2011). Referential signaling is important to identify because it could indicate that the sender has voluntary control over what it communicates, as opposed to its communication being just an involuntary, affect-based response. It is also argued to be a step forward toward animal communication having more in the way of semantics – signals representing entities in the environment. Vervet monkeys produce acoustically distinct alarm calls when they detect three different classes of predator (eagle, leopard, and snake), and context-free playbacks of those alarm calls produce functionally appropriate escape or information-gathering information in receivers, supporting the notion of referentiality in these calls (Cheney and Seyfarth 1990). However, the concept of referential signals remains controversial (Wheeler and Fischer 2012). In many cases it is unclear if the animals are using different variants of calls to signal about aspects of their environment, or if the differences in these calls are a result of motivational changes in the sender as a response to environmental differences.

Multimodal Signals It has become clear that a great deal of animal communication involves senders producing changes in their behavior in

more than one modality simultaneously, with the result that receiver behavior can potentially be influenced by one or both components of the signal (Partan and Marler 2005). A well-studied example involves the physical changes to head and body postures when animals produce sounds, such as calls of anurans and insects, and songs of birds. Receiver behavior can potentially be influenced by the acoustics of the sound produced, the visual patterns of the sound generation and changes in body posture, or both. Importantly, the different modalities involved in a multimodal signal may influence receivers in nonadditive ways, suggesting an emergence of information from the different components generated by different modalities (Partan and Marler 2005).

Cues

In their normal activity, animals produce considerable variation in movement speeds, body postures, limb and head orientations, and so forth. This variation in body part orientation and movement can allow an observer (the receiver) to predict behavioral tendencies of the target individual (the sender). This is the meaning of a cue in animal communication – phenotypic variation in a sender that causes a reaction in a receiver, where that reaction's function is to be caused by that phenotypic variation even though the phenotypic variation itself does not function to cause that reaction (Scott-Phillips and Kirby 2013). In other words, sender variation in behavior did not evolve to communicate to the receiver, but the receiver gains information about the sender nonetheless. For example, sleeping behavior in human infants serves as a cue to likelihood of activity (or lack thereof) to others in the environment, even though sleeping behavior did not evolve to communicate to another individual the likelihood of the level of activity of the sleeping individual. Cues, unlike signals, have not evolved for the particular function they serve (Maynard Smith and Harper 2003); cues benefit the receiver and not the sender.

Cues are used by receivers for multiple reasons – social and nonsocial. Individuals use cues

from potential predators to determine predation risk. Predators produce cues that could indicate the level of risk that the predator may entail. For example, for many small mammals and birds, a detected hawk that is sleeping represents a different level of threat compared to a detected hawk that is awake, and both of these hawks are lower levels of threat than a flying, actively hunting hawk. It is likely not advantageous to the predator to reveal cues that could indicate risk to its intended prey, but the variation in body part orientation and movement related to variation in life's activities (hunting, resting, courting, etc.) cannot always be concealed. As one key example, many species are readily able to discriminate the head orientation of a predator. For example, both Carolina chickadees (*Poecile carolinensis*) and tufted titmice (*Baeolophus bicolor*) avoid a feeder more and call differently if a potential predator has its head oriented toward a feeder rather than oriented away from the feeder (Kyle and Freeberg 2016). Beyond head orientation, many species seem to be especially sensitive to the eyes of others, including predators. Eye gaze is thought to be one of the most important cues used by prey species to determine what a predator is attending to and the level of threat posed by that predator. In predator species the eyes are especially salient, with most predator species having forward-facing eyes, as opposed to the lateral eyes of many non-predatory species. It seems that many species are able to pay attention to eye shaped objects more than other objects.

Assessment of eye gaze is not only important to identify predation risk but is also important in social interactions. In many primate species, individuals can identify whether another individual is visually paying attention to them or to an important stimulus in the environment. Experiments have revealed that numerous primate species can follow a conspecific's eye gaze toward a goal. Many have argued that the ability to understand where an individual is looking is a crucial step in the evolution of the theory of mind in humans (Calder et al. 2002). Humans also seem to be particularly fixated on the eyes and eye gaze of other humans. The fact that humans, nonhuman primates and birds all pay attention to eye gaze

suggests that it is an important communicative feature in perception of sender cues that should be examined more carefully.

Evolution of Signals

One of the most fundamental reasons why animals communicate is that it aids in their survival and reproduction capability. They need to find food sources, attract and compete for mates, fight with any intruders and competitors that threaten their resources, and avoid or defend themselves from predators. Many of these requirements result in changes in arousal and emotional state in animals, and many of these changes could also result in cues to receivers. Charles Darwin addressed the topic of communication chiefly through his examination of emotional expressions. Darwin argued that emotional expression was (at least at some point) beneficial for many types of animals (Darwin 1872). A growling dog may intimidate another dog into abandoning a food source without a fight. A distress call from a newborn chimpanzee would likely provoke the caregivers into both attending to the newborn and investigating the source of their distress. Thus, communicating about motivational states is assumed to be helpful to individuals in general.

Darwin provided three principles of emotional expression to help explain how they became part of evolutionary processes that result in communicative signals: *serviceable habits*, *direct action of the nervous system*, and *antithesis*. These principles have been extended by decades of subsequent research – particularly in the field of ethology. Beginning with *serviceable habits*, consider the classic example of a dog (or almost any terrestrial mammal, for that matter) attacking another individual. A key means by which a dog attacks another is by biting it. To bite another individual effectively, a dog must carry out two precursor movements. First, the dog must open its mouth to make the bite possible. Second, the dog must pull its lips back away from its teeth, exposing the teeth for the bite. Thus, a receiver not wanting to fight could benefit by paying attention to the sender's initial cue of an open mouth and bared

teeth in the short time period prior to an attack involving biting. The benefits gained by both parties not actually having to fight, but by solving the agonistic interaction through this “open mouth/teeth baring” cue, would generate strong selection pressure for that cue to evolve into an even stronger and less ambiguous signal of likelihood of attack. This evolutionary process is known as ritualization.

In his view of *direct action of the nervous system*, Darwin argued that many emotional expressions were rooted in the physiology of the organism. Each organism depends upon numerous homeostatic and nonhomeostatic processes to maintain biological functioning in response to a dynamic environment to achieve its biological goals. Some of the changes in the body that result from changes in neurophysiological functioning are observable, including erection of feathers or hair, dilation of pupils, yawning, sweating, and defecation/urination. Finally, the principle of *antithesis* explains how the opposite changes in neurophysiology (or serviceable habits, for that matter) are also likely to provoke opposite effects on the resultant behavior. For example, hormone-activated aggression causes muscles to become tense, whereas the opposing, nonaggressive states promote relaxed muscles to preserve energy. As raised above, cues stemming from these three principles of emotional expression can evolve into signals, often through the process of ritualization (Bradbury and Vehrencamp 2011). Through natural selection, these cues can evolve to become “sign stimuli” – more conspicuous and stereotyped signals to other animals that invoke specific behavioral replies. These cues and signals can be integrated into higher-order cognitive systems in receivers that control communicative salience (Dall et al. 2005). This integration between attention mechanisms and the sign stimuli can generate selection biases in the receiver.

The “sender-precursor model” described above has explained that signal evolution occurs by receivers detecting cues of producers that are beneficial to those producers (and often to the receivers) and processes like ritualization (Bradbury and Vehrencamp 2011). Alternatively, the “receiver-precursor model” posits that

receivers have sensory biases and prefer specific types of behaviors or physical appearance in others. These biases are shaped by natural selection in a number of ways – for example, in species that rely heavily on the ingestion of orange fruits, greater perceptual acuity for orange color as a food item may result in stronger preferences for and biases toward orange color in general. Sensory exploitation occurs when senders evolve traits that receivers prefer (Bradbury and Vehrencamp 2011).

Conclusion

Throughout this entry, the general topic of communication has been addressed in a few different ways. Distinctions between signals and cues were clarified, major types of signals used by senders were outlined, the use of “information” as a framework (or in some cases, measure) of communication was described, and the evolution of signals from cues was overviewed. However, despite the fact that communication is such an essential and pervasive phenomenon found throughout the animal kingdom, this entry leaves many important questions unresolved (a number of which are addressed in subsequent entries). For example, how similar, or dissimilar, is human communication compared to animal communication (D’Ettorre and Hughes 2008; Tomasello 2008)? In humans, much communication concerns objective information – such as the location or identity of a desired item. Some of this objective information can reflect sender emotional state – receivers can typically assess when senders are happy or angry, for example. In addition to objective information, human senders can communicate abstract and subjective information – individual thoughts, perceptions, sensations, and feelings about idiosyncratic experiences and personal understandings of the world. Human senders can also communicate about communicating, such as the request by management for an audience of people to silence their cell phones prior to the start of a performance, or the encyclopedia entries in the current volume. To what extent can animals communicate abstract information to

others in ways similar to human language and communication?

Along these same lines, is animal communication primarily or exclusively related to communication about affective states and propensity to engage in certain behavior? Or is some animal communication truly referential, whereby certain signals represent important classes of environmental stimuli, such as predators (Wheeler and Fischer 2012)? Animals can vary their signaling behavior depending upon the particular audience of receivers they detect in the environment. Are these “audience effects” indicative of volitional control and strategic flexibility in signal use by senders, or of signal production in response to changes in affective state due to variation in social environments? Do animals communicate about communication, such as through the use of a signal to alert a receiver that another signal is coming (Tomasello 2008)? To what extent do the more basic sender–receiver interactions described here capture the signaling interactions – and the information receivers can glean from such interactions – in complicated communication networks (McGregor 2005)? How flexible are signaling systems in animal communication, from both developmental and evolutionary perspectives? These are currently topics of intensive research, and this entry could not hope to do them justice here due to space constraints. Other entries in this volume will touch on these important topics, however, and if this entry has successfully communicated the fundamental role of communication in animal lives, readers of this entry should be encouraged to read on.

Definition

Cross-species comparative analysis of same-sex sexual behavior.

Introduction

If sex is the engine that drives Darwinian evolution, why would a variety of animal taxa invest in nonconceptive sexual behaviors that do not directly contribute to reproduction? This section aims to address this evolutionary conundrum by focusing on the cross-species comparative analysis of homosexual behavior, in an attempt to shed further light upon the origins and evolution of human homosexuality.

Phylogeny of Homosexual Behavior

Despite its apparent lack of fitness benefits, same-sex sexual activity is broadly distributed across the animal kingdom. Descriptive reviews indicate that hundreds of species of mammals, birds, reptiles, amphibians, fishes, insects, spiders, mollusks, nematodes, and other invertebrates engage in extremely diverse homosexual behavioral patterns, including courtship displays, manual-genital, oral-genital, and genital-genital stimulations, and mounting interactions, with pelvic thrusting and even intromission between same-sex partners (Bagemihl 1999). However, the cross-species distribution and expression of same-sex sexual activity is uneven. First, the

frequent, prevalent, and enduring occurrence of homosexual behavior in some species contrasts with its seeming absence, or at least obvious scarcity, in others. Second, some species exhibit only female-female or only male-male sexual behavior, whereas other species exhibit both. Third, several proximate and ultimate hypotheses have been proposed to account for the diverse manifestations of same-sex sexual interactions in different species, such as the lack of opposite-sex sexual partners, the pursuit of immediate sexual reward, the practice by immature individuals for heterosexual sex, or the achievement of social goals (e.g., dominance demonstrations, alliance formation, or tension regulation; Poiani 2010; Sommer and Vasey 2006). Only systematic comparative research aiming to quantitatively examine the factors that contribute to the emergence and expression of homosexual behavior among animal taxa can provide some solutions to this evolutionary puzzle (Sommer and Vasey 2006; Vasey 2007).

One of the most powerful methodological tools to explore the origins and evolution of biological features is the phylogenetic comparative approach (Martins 1996). By superimposing the phenotypic trait of interest over a robust phylogenetic tree based on molecular data and encompassing many related species, researchers make parsimonious historical inferences about how this trait originated and changed in a step-by-step manner over time. Phylogenetic analyses are particularly useful to reconstruct scenarios for the evolutionary history of behavioral traits, which do not leave any direct fossil traces. They can be used to decide whether similar behavioral patterns are due to common ancestry or the result of independent adaptations to similar environmental pressures (Martins 1996). Such a comparative approach should be relevant to the evolution of homosexual behavior, because it can distinguish adaptive from nonadaptive traits by indicating which ones have predated, accompanied, or followed the modification of some of their structural and functional attributes. Moreover, just like play behavior (cf. Pellis and Iwaniuk 2000), the lack of functional constraints, and thus the flexibility and

versatility of same-sex sexual activity, makes it a good candidate for phylogenetic studies. In principle, reconstructing scenarios for the evolution of homosexual behavior requires well-established and often composite phylogenies that are not directly based on sexual characteristics.

Yet, comparative investigations of the evolution of homosexual behavior are extremely rare and limited to birds and mammals. A phylogenetic analysis of the frequency and form of same-sex courtship and mounting behaviors in 80 avian species showed strong associations between such homosexual interactions and both social mating system and developmental mode, but with marked differences between males and females (MacFarlane et al. 2007). More specifically, female-female sexual behavior mainly occurred in socially monogamous species that produce precocial offspring at hatching, whereas the frequency of male-male sexual behavior significantly increased with the degree of polygamy of the species, regardless of the developmental state at hatching. Another study conducted on 93 avian species showed a consistent relationship between sex-specific relative parental care and the frequency of both male and female homosexual behavior: When females provide less care than males, female-female sexual behavior is more frequent, and when males provide less parental investment than females, male-male sexual behavior is more frequent (MacFarlane et al. 2010). Poiani (2010) tackled the daunting task to examine the effect of social, life history, and ecological factors in the frequency of same-sex mounting across 72 bird species and 107 mammal species (including humans). In birds, he found that homosexual mounting was negatively associated with the size of the social unit and positively associated with adult male-biased sex ratio, increased sociality, and increased level of dominance. In mammals, he found that homosexual mounting was negatively associated with social unit size and relatedness between partners and positively associated with polygamy. In both birds and mammals, he found that same-sex mounting was

positively associated with social sexual segregation (i.e., spatial distancing between the sexes for part or even most of the year). Comparative tests showed that Poaini's (2010) *Synthetic Reproductive Skew Model of Homosexuality* fit better the avian than the mammalian data set, even though homosexual mounting is more prevalent in mammals than in birds. This suggests that same-sex mounting is more complex in mammals than in birds. The relatively higher prevalence of homosexual behavior in mammals is likely to be associated with a greater degree of sociality, polygamy, and cooperative breeding in this taxon (Poaini 2010). A recent phylogenetic study focusing on nonhuman primates showed that the frequency of same-sex genital contact was positively associated with social complexity, and this effect was stronger in males than in females (Fernandes et al. under revision).

Phylogenetic research on homosexual behavior is still hampered by several types of limitations that need to be overcome. The first type is both observational and theoretical: The validity of the comparative method rests on the ability of researchers to correctly detect, identify, and record this behavior in their study species when it occurs. This is not trivial because nonadaptive behaviors, such as same-sex sexual activity, are by definition devoid of major fitness consequences and thus tend to be dismissed as idiosyncratic, anecdotal, and not worth of research interest. As a result, the occurrence of homosexual behavior may be underreported in cross-species comparative reviews. The second type of limitation is logical: Absence of evidence is not evidence of absence. Because it is comparatively easier to prove the occurrence of a behavior than its absence, phylogenies of homosexual behavior are likely to contain false negatives (e.g., due to differential research effort when comparing species). The third type of limitation is methodological: The phylogenetic analytical tool kit is broad, and there is no universal consensus on whether the dependent variable (i.e., homosexual behavior) should be dichotomized (i.e., presence/absence) or classified on a frequency scale, divided by sex

(i.e., female-female versus male-male sexual behavior) or not, and superimposed on a specific cladogram to control for the evolutionary relatedness across species, as well as how phylogenetically independent contrasts should be calculated (cf. Martins 1996). All these decisions may affect the results of the interspecific comparison and their interpretations. Finally, it is important to remind the reader that these cross-species comparative analyses are based on homosexual *behaviors*, and there is currently very little to no evidence that homosexual *behavior* in nonhuman animals reflects homosexual *orientation*. Rather, it likely reflects animals' potential for bisexual behavior, which exists, for example, in several primate species (Dixson 2012). When considering how results obtained from animal research on homosexual behavior may apply to the evolution of human sexuality, one should keep in mind that although reproductive behaviors in humans and animals likely share some homologous features, nonconceptive sexual behaviors among different species may be analogous. For instance, exclusive same-sex sexual orientation has not been documented in any free-ranging nonhuman primate species. As such, the study of homosexual *behavior* in nonhuman primates may inform us about the evolution of homosexual *behavior* in humans but may shed only limited light as to why exclusive homosexuality evolved.

Conclusion

Overall, cross-species comparative studies suggest that same-sex sexuality is not an evolutionarily uniform phenomenon. Instead, it appears that multiple analogous forms of homosexual behavior have evolved, underlain by different developmental pathways, sociodemographic settings, motivational processes, functional outcomes, and phylogenetic histories both within and between species (Vasey 2007). Therefore, evolutionary explanations of homosexual behavior are contingent on the implementation and full integration of two complementary levels of

analysis, namely the phylogenetic (i.e., historical) and functional (i.e., adaptive) perspectives (Vasey 2007). Some forms of same-sex sexual activity may have no adaptive value whatsoever, while others may be nonsexual acts that are executed to serve social functions. As such, we should not expect any one evolutionary explanation for same-sex sexual behavior to account for the diversity of this phenomenon. Indeed, attempts to make unifying interspecies generalizations about the evolution of homosexual behavior may be misguided and misleading.

Compensatory Mate Retention Tactics

Alastair P. C. Davies
Regent's University, London, UK
Lakehead University, Thunder Bay, ON, Canada

Definition

Compensatory mate guarding tactics are defined as mate guarding tactics such that the use of one tactic compensates for the lack of use another tactic.

Introduction

Once an individual secures a long-term mate or romantic partner, the individual has the adaptive problem of retaining the mate. As the word “retain” may be generally defined as “to keep possession or use of”, mate retention tactics might be considered to have as their aim the prevention of a mate from permanently defecting from or abandoning a long-term relationship. Although they do serve this purpose, mate retention tactics can also reduce the likelihood that a long-term mate will commit an infidelity or temporarily defect from a relationship by engaging in extra-pair copulations (EPCs). Mate retention tactics are, therefore, considered to be tactics that serve both purposes (e.g., Buss 1988; Shackelford et al. 2005). It follows that whether a particular mate retention tactic is aimed at preventing a partner from permanently abandoning a long-term relationship or engaging in EPCs depends on the motivation of the individual employing it.

In a seminal article, Buss (1988) devised a taxonomy of mate retention. His classification included two categories, subsuming six strategies, subsuming 19 tactics, subsuming 104 acts. For instance, the category *Intersexual Manipulations* subsumed strategies including *Negative Inducements* that subsumed tactics including *Threaten Infidelity* that subsumed acts including *He flirted with another woman in front of her*. Incorporating the acts, Buss devised a *Mate Retention Inventory* (MRI) to assess the frequency with which individuals employ the 19 tactics. Subsequently, Buss et al. (2008) developed a short form of the MRI (*MRI-SF*). The *MRI-SF* assesses the frequency with which individuals employ the 19 mate retention tactics but includes only two acts per tactic.

Notwithstanding Buss' (1988) taxonomy, there remains controversy over the classification of mate retention tactics. A notable example concerns whether *mate retention* is synonymous with *mate guarding*. Prior to Buss, taxonomies considered the terms to be synonyms as mate guarding was considered to comprise any tactic employed by an individual to prevent the individual's mate from being fertilized by intrasexual rivals (e.g., Thornhill and Alcock 1983). However, these taxonomies were based on non-humans, notably insects, and the tactics considered included female mimicry, mate plugs, and vibratory signalling; tactics not typically associated with humans.

Buss' (1988) taxonomy was the first to solely consider mate retention tactics used by humans. Unlike previous taxonomies, it subsumed *mate guarding* under *mate retention*. Buss argued that mate guarding may not reasonably be considered to encompass certain tactics of mate retention; “Tactics may be subtle, including dissuading potential competitors, luring one's mate with positive inducements, or even rendering one's mate less attractive or evocative to competitors. These tactics appear to fall outside the category of ‘mate guarding’ but are accurately subsumed by the category of ‘mate retention’” (p. 292). To support his classification, Buss used the term *direct guarding* to differentiate his definition of mate

guarding from the broader definition previously associated with the term. Under *direct guarding*, Buss subsumed the following tactics: *Vigilance*, subsuming acts including *He asked his friends to check up on her*; *Concealment of Mate*, subsuming acts including *He refused to introduce her to his same-sex friends*; and *Monopolization of mate's time*, subsuming acts including *He insisted that she spend all her spare time with him*. In light of Buss, it may not be reasonable to consider *mate guarding* as a synonym for *mate retention*. Alternatively, there may be value in following Buss and making a distinction between the inclusive term *mate guarding* and the more restrictive term *direct mate guarding*.

Although both sexes wish to prevent a partner from engaging in EPCs, for a man, a partner's engagement in EPCs may lead to him being cuckolded or unknowingly raising the children of other men. For men, therefore, mate retention tactics also serve as anticuckoldry tactics. Not all anticuckoldry tactics, however, are mate retention tactics as not all serve to prevent a partner from permanently abandoning a relationship or engaging in EPCs. Rather, certain anticuckoldry tactics serve only to reduce the likelihood that offspring will result from an EPC in which a partner has already engaged. For instance, Baker and Bellis (1993) found that the greater the length of time that a couple had spent apart since their last copulation, the greater the amount of sperm that men inseminated into their partners. Because the greater the length of time that a couple has spent apart, the greater is the likelihood that the woman will have engaged in EPCs, Baker and Bellis' finding suggests that the aim of depositing a greater amount of sperm is to increase the likelihood that the men's sperm will outcompete any rivals' sperm to fertilize their partners' eggs. Further, Shackelford et al. (2002) investigated if men have evolved psychological adaptations to reduce the likelihood that a partner's EPCs will result in offspring. They found that the greater the proportion of time that men had spent apart from their partners since their last copulation, men reported the

following: a greater attraction to their partners, other men found their partners more attractive, and a greater desire to have sex with their partners. Shackelford et al.'s findings suggest that these psychological adaptations serve anticuckoldry purposes by motivating men to, as soon as possible, place their own sperm in competition with any rivals' sperm that may already be in their partners' reproductive tracts. It follows that while men's anticuckoldry tactic of placing as much sperm as possible in their partners' reproductive tract as soon as possible serves to prevent extra-pair fertilizations, it serves neither to prevent a partner from engaging in EPCs nor to prevent a partner from permanently abandoning a relationship. It, therefore, cannot be considered to be a mate retention tactic.

Compensatory Mate Retention Tactics

Shackelford, Goetz, Guta, and Schmitt (2006) investigated the relationship between the frequency of men's use of the anticuckoldry tactics of mate guarding and in-pair copulations. They labelled as "compensatory," tactics such that the use of one tactic compensates for the lack of use another tactic. Shackelford et al. stated that there exists a negative correlation between the frequencies of use of compensatory anticuckoldry tactics.

Following Shackelford et al. (2006), the current article defines "compensatory" mate retention tactics as those such that the use of one tactic compensates for the lack of use another tactic. It is, therefore, assumed that there is a negative correlation between the frequencies of use of compensatory mate retention tactics.

The literature is not directly informative regarding the tactics that are used in a manner that is compensatory as defined here. Nevertheless, it is reasonable to speculate regarding factors that may lead particular individuals to employ particular mate retention in such a manner. For instance, some individuals may have insufficient resources to use the tactic "resource display" but

may be able to use the tactic “appearance enhancement” as a compensatory tactic. For those individuals, there will be a negative correlation between the frequency of use of “resource display” and “appearance enhancement.” Similarly, some individuals may not have the physical stature to use the tactic “violence against rivals” but may be able to use the tactic “resource display” as a compensatory tactic. For those individuals, there will be a negative correlation between the frequency of use of “violence against rivals” and “resource display.” Future research might, therefore, measure individuals along traits such as resources, physical attractiveness, and physical stature and ask them to report their frequency of use of various mate retention tactics. Tests might then be conducted to assess whether individuals who score low on particular traits have a low frequency of use of mate retention tactics associated with those traits and who score high on particular traits have a high frequency of use of mate retention tactics associated with those traits. As the intensity with which mate retention tactics are employed has been shown to depend on the relative mate values of partners and the length of a couple’s relationship (e.g., Buss and Shackelford 1997), there would be value in future research investigating if those factors moderate the use of mate retention tactics.

Conclusion

The literature on mate retention among humans is relatively new and the only taxonomy existing for it is that provided by Buss (1988). The primary aims of the current article have, therefore, been to clarify the following: the definition of the term *mate retention*, of which tactics mate retention is comprised, and the definition of *compensatory mate retention tactics*. By doing so, it is hoped that the current article will play a part in eliminating inconsistencies between future studies of mate retention and, therefore, lead to an improved understanding of the topic.

Competition Between Groups

Alexander Shkurko

Ulyanovsk/Nizhny Novgorod, Russia

Synonyms

[Between-group competition](#); [Intergroup competition](#); [Intergroup conflict](#)

Definition

Social behavior, in which individuals jointly fight for resources against another group of individuals or when social groups pursue mutually exclusive goals

Introduction

Cooperation and competition are two basic forms of social behavior. In the broad sense, competition relates to any types of conflict between agents. In a more narrow and strict sense, competition takes place only when agents strive to acquire the same resource or when achieving a goal means preventing others from achieving their goals. Margaret Mead, an American anthropologist, suggested that individualistic behavior, i.e., a goal-directed behavior not referring to others, is the third basic type of behavior typical for group life (Mead 1937, p.16). One has to note however that the behavior can be individualistic at the operational level, i.e., in terms of how the action is performed, whereas the goals can be either cooperative or competitive.

A number of influential theories, from Darwinian evolution theory and Hobbesian “war of all against all” to contemporary rational choice theories, consider competition as the core of all social behavior and the evolution itself. Altruistic or cooperative behavior in these approaches is often considered as a by-product of competition serving agents’ fitness and/or self-interest. By agents

these approaches typically mean individual agents. But for humans and some other species, social behavior is mainly organized around groups and is conditioned by group membership. As well as in the evolution theory where approaches stressing the group-based reality of social life (kin selection and group selection theories) appeared, the understanding of competition in human societies makes it necessary to consider competition between groups in addition to competition between individuals.

Evolution of Between-Group Competition

Although the most complex forms of intergroup competition are present in modern societies, its roots can be found in archaic human communities and nonhuman species. In nonhumans, individuals often form coalitions, both altruistic, e.g., in the form of protecting a related one against the third party, and more opportunistic, in the form of joining a stronger rival. However, competition between large groups is relatively rare in animals (Van Hoof 1990; Willems and van Schaik 2015). The most common types of between-group conflict are the competition of groups over territory, food, or access to mates. Same-specie groups may struggle for the territory when the population density increases but typically tend simply to avoid direct contact. The most shining examples of intergroup competition in nonhumans take place among the simplest species of social insects, on one hand, and the most developed species of mammals, namely, primates (Van Hoof 1990; Wilson and Wrangham 2003). Competition among males over territory, food, and females was found to be a form of social behavior in chimpanzees, thus indicating the possible roots of intergroup aggression in human societies (Wilson and Wrangham 2003).

In early humans the same types of intergroup competition became more common than in non-human species. Primitive wars, an extreme form of intergroup competition, are characterized by the great diversity. Some intergroup conflicts are

very similar to those of other species and can be directly related to increasing access to basic resources. At the same time, intergroup conflicts often take the form of “pure aggression,” in which no territory or other resources are conquered (Van Hoof 1990). Wars among primitive tribes can be rationalized by their members as having mystic- or “pride”-related motives. The diversity of forms and overt motives underlying intergroup wars, which are often very costly, leads to the hypothesis that humans developed specific psychological mechanisms supporting group-based forms of competition.

Between-Group Competition and Within-Group Cooperation

The distinctive feature of human intergroup competition is that it is possible only if the members of a group cooperate with each other. In other words, within-group cooperation is a necessary prerequisite for between-group competition. Moreover, human cooperation goes far beyond cooperation between closely related individuals typical in non-humans and explained by kin selection mechanisms. The exceptional ability of humans to cooperate with unrelated others is defined as their “ultra-sociality,” which is supported by psychological rather than genetic factors (Tomasello 2014).

These two distinctive features of human social life, prevalence of intergroup competition and exceptional intragroup cooperation, can be closely related to each other. More specifically, intergroup competition and conflict have been proposed to play the key role in promoting human cooperation within groups. A number of psychological experiments supported this view and described mechanisms preventing group members from violation of group norms and egoistic behavior. For example, a study by Burton-Chellaw et al. (2010) showed that introducing intergroup competition context increased within-group financial contributions. Individuals in these situations are more inclined to perceive other group members as cooperators rather than

competitors. This pattern of behavior is regulated by specific emotional reactions. Participants of an experiment felt more guilty when their contribution to the group was less than that of other group members and, on the other hand, felt more angry when their contribution was larger than that of others. Similar results were obtained in other psychological experiments (e.g., Puurtinen and Mappes 2009). These results support the view that when a higher-level competition between groups is introduced, it reduces costs associated with cooperative behavior and makes it more probable.

A more specific evolutionary explanation of relations between intragroup cooperation and intergroup competition was proposed within the so called Male-Warrior Hypothesis (Van Vugt et al. 2007). According to it, males and females evolutionary developed different psychological mechanisms supporting within- and between-group behavior. Males developed the ability to cooperate and coordinate their behavior to jointly increase their access to reproductive resources, i.e., females from a different group. Although engaging in overt conflict with an out-group is risky, for a group, male deaths are less important than female deaths, whereas access to additional reproductive resources is a valuable benefit. Male-warrior hypothesis is confirmed by numerous facts indicating that intergroup conflicts are mainly driven by males' behavior and that males are the primary targets of such conflicts (McDonald et al. 2012). The selection mechanisms underlying gender differences in intergroup behavior are supposed to produce different patterns of behavior between males and females and psychological reactions. For example, in response to out-group males, men are more suspicious, aggressive, and xenophobic and tend to strive for group-based social hierarchies, whereas women's reactions are more guided by fear and avoidance behavior resulting from the risk of sexual coercion (McDonald et al. 2012). Moreover, according to the theory, men should build stronger ties with in-group members than women.

The two approaches, described above, both stress the close link between intergroup

competition and intragroup cooperation although they differ in generality and supposed mechanisms. However, the first one is not limited by overt conflict relations between groups and more clearly states that the evolution supported a general psychological mechanisms for group-based cooperation and competition rather than more specific ones supposed by male warrior hypothesis. At the same time, the latter, stressing important gender differences in group-based behavior, doesn't necessarily mean that all intergroup competition should be considered as a war for reproductive resources available for a group. Rather, it stresses that this type of conflict was evolutionary crucial for the development of psychological mechanisms initiating and maintaining intergroup conflict.

Competition Between Which Groups?

Evolutionary explanation of group-based behavior is mainly driven by the kin selection theory. Concerning the problem of intergroup competition, it states that individuals may use the support of a group to increase their fitness and reproductive success. Even if an individual takes a risk of death during the intergroup conflict, the success of a whole group in obtaining additional resources will increase the probability of disseminating genes shared with close relatives. This theory however faces difficulties when cooperation between unrelated others are under considerations.

Indeed, in modern societies intergroup competition is very diverse and covers relations between small and large groups not related to kinship. Competition is common between nations, firms, sport teams, and research labs or even between arbitrary groups defined by very superficial and contextual features. Moreover, even in archaic societies kinship organizations could be very complex and provide opportunities to various patterns of group relations (Mead 1937). Competition and conflict between relatives are also a potential problem for kin selection theory (West et al. 2002).

The easiness, with which intergroup-competing emotions and behaviors can be induced in humans, indicates that the underlying

psychological mechanisms are very general and universal. The social identity theory argues that the mere social categorization, i.e., the distinction between in-group and out-group, is sufficient to trigger intergroup competition whatever the rationale for group boundaries is (Tajfel and Turner 1979). From the point of view of evolutionary psychology, the easiness and universality of intergroup-competing intentions and behaviors mean that the evolution of human sociality favored psychological mechanisms supporting general ability to cooperate with unrelated others rather than groups based on close kin relations. This view corresponds more to the group selection theory (Wilson 2006) and the theory of social cognition (Kinzler and Spelke 2007) stressing that humans developed specific abilities to form and recognize variety of group membership and intergroup relations.

Conclusion

Competitive behavior is common in nature and is directly explained by the key evolutionary mechanisms. A more specific form of competition is competition between groups, which is a distinctive feature of human societies. Even more importantly, intergroup competition in humans extends far beyond competition between close relatives and is supported by universal psychological mechanisms, which make it easy to trigger perception of social relations in terms of group membership and group-based competition. The basic explanation of such an evolutionary solution is that introducing intergroup competition context stimulates cooperation within a group, which is crucial for human sociality. Yet there are facts supporting the view that there are important gender differences in intergroup perceptions, emotions, and behaviors resulting from the different selection pressures in the past.

Competition for Parental Investment

Venla Berg
Population Research Institute, Väestöliitto –
Finnish Family Federation, Helsinki, Finland

Synonyms

[Brother](#); [Sibling](#); [Sibling spacing](#); [Sister](#)

Definition

Parental investments are resources that a parent directs to the benefit of any single offspring at the cost of directing resources to other fitness-enhancing targets. Siblings, who share the same parents, represent competition for parental investment. Because an individual is always more related to herself than to her sibling, she will try to extract parental investment to herself at the cost of siblings. Competition for parental investments is a source of sibling rivalry.

Introduction

Through mutual parents, siblings share genes and parental resources. Humans have an exceptionally slow maturation process, and children are dependent on others long after weaning. In addition, humans have exceptionally short average birth intervals compared to our nearest relatives, great apes, resulting in multiple dependent offspring to be taken care of simultaneously. Hence, even though shared genes are likely to promote cooperation and altruism between siblings (see Hamilton 1964), siblings represent competition for

resources that are vital for survival and successful development.

Parental Investment and Parent–Offspring Conflict

Parental investment is defined as any parental actions or resources invested on the benefit of one child at the cost of investing in other fitness-enhancing actions (Trivers 1972). Parental investment is a limited resource, and additional offspring reduces investment in any single child. Parents are expected to always invest maximally, but from the offspring's point of view, any parental investment directed to siblings (50% relatedness) against investment in oneself (100% relatedness) is unbeneficial. Therefore, parents and offspring are in conflict on how much the offspring wants to extract parental investment and how much the parent is able or willing to invest (Trivers 1974). Siblings represent competition for parental investment. In addition, a parent may choose to invest disproportionately in offspring with greater perceived reproductive value (Jeon 2008), further intensifying the competition between siblings.

Birth Intervals as Components of Sibling Rivalry

Compared to great apes of similar body size than humans, humans have exceptionally short average birth intervals (Galdikas and Wood 1990). Short birth intervals combined with an exceptionally long maturation process result in having to take care of multiple dependent offspring simultaneously. Birth intervals affect the competition for parental investment and alloparental care (care provided by other people than the mother) between siblings to a great extent. In hunter-gatherer societies, birth intervals that fall short of 3–4 years, considered to be the species-typical interval for humans, are associated with increased mortality of both children defining the

short interval (e.g., Blurton Jones 1987). Short intervals supposedly hinder the mother to recover from previous pregnancy, leading, for example, to increased risks of prematurity and reduced fetal growth even in affluent industrialized societies (Conde-Agudelo et al. 2006). Short intervals also dilute care during the early years of intense needs of infants, affecting both the child born prior to and the child born after a short interval.

Especially in nutritionally challenged environments, lactational amenorrhea usually prevents a new pregnancy from beginning too early from a maternal perspective. However, from the previous child's perspective, an even longer birth interval than would be beneficial for the mother, is preferred. Infant's night waking, and continued nighttime breastfeeding, may be a sibling competition mechanism that increases birth intervals in the benefit of the infant (Haig 2014).

Indeed, shorter birth intervals seem to intensify sibling competition. Shorter intervals are associated with more affect-intense and conflict-burdened sibling relationships: siblings closer in age fight more (e.g., Minnett et al. 1983). Children of similar age have more similar needs and compete for parental (and possibly allomaternal) investment more than siblings who are of different ages. In addition, the number of siblings in general is inversely associated with individual's cognitive skills, academic performance, and adulthood income in postindustrialized societies (Steelman et al. 2002), and in high-fertility high-mortality societies, with child survival (Lawson et al. 2012). These negative effects of siblings on child development, however, are less pronounced with longer birth intervals.

Conclusions

Sibling rivalry is one consequence of competition for parental investments. Competition is intensified with more siblings and especially with closely spaced siblings. Individuals born prior to or after a shorter birth interval show signs of reduced

fitness, such as increased mortality or poorer reproductive quality.

Competition for Resources Desired by Females

Stephen Heap
Jyväskylä, Finland

Synonyms

[Female intra-sexual competition for resources and mates](#); [Male-male competition for resources](#); [Resource-defense polygyny](#)

Definition

Intra-sexual competition (in both females and males) for access to the resources necessary for female reproduction and parental investment.

Introduction

In the context of sexual selection, females compete more intensely for resources and males compete more intensely for mates. Females can compete with each other for access to resources and/or express biased selection for males that control resources. On the other hand, males can compete for mates by controlling the resources that females desire.

The nature and distribution of the desired resources can influence the institution of different mating systems (who mates with whom). In particular, males that can monopolize resources can also monopolize mates. This can establish a conflict of interest between males and females, as males benefit by having more mates and females benefit by limiting resource competitors. However, females can offset the costs of resource competition by investing in the quality of their offspring and their subsequent inclusive fitness. Thus, female competition for resources is best understood with a multigenerational framework.

Females Compete with Each Other over Resources

Female mammals need resources like food, shelter, and protection to reproduce. Competition for these resources is a significant selection pressure, and females possess a variety of adaptations to secure their needs. Behavioral strategies range from low to high levels of aggression but tend to be more indirect and lower risk than males. This is because mothers must survive to produce offspring and provide maternal care (at least for gestation and weaning). Females thus have plastic competitive strategies that vary with demographic and ecological factors (e.g., population density, socioeconomic conditions, group membership). Strategies can be highly aggressive when resources are especially valuable and during territory defense. But otherwise females (especially those in stable social groups) use dominance, threats, and coalitions to secure resources for themselves and their offspring (Fisher 2013; Liesen 2013; Stockley and Campbell 2013).

Competition among social females may also be balanced by the interdependent nature of their relationships. Females must compete among each other for resources and mates, but successful reproduction also involves their mutual cooperation. Thus, females may need to contend with a trade-off between fostering cooperative interactions while also competing over limited resources (Fisher and Moule 2013).

Females can indirectly compete over resources by mating with the males that control them. If males provide differential access to resources, care, and protection, then females can compete with each other over quality males – just as males conventionally compete with each other over females (Clutton-Brock 2009; Stockley and Bro-Jørgensen 2011; Stockley and Campbell 2013).

When females are allowed free choice in their mates, they act to maximize genetic quality and the quality of held resources. If males provide no resource value, females can select males with better quality genes, and better quality males accumulate more females. If males control

resources but there is no variation in value, then females can compete for the best genes but distribute monogamously for resources. However, if males vary in resource value, then females also shop for resource quality.

Males with many resources can support multiple females, and females may share their mates. But resource access decreases with additional female competitors. Thus, female selection may take place in relation to a “polygyny threshold”: the level of resources at which it is better to accept polygyny with a rich male over monogamy with a poor male. Even under polygyny, it is in the female interest to limit the number of other females that have access to a male’s resources and compete with those that do (Emlen and Oring 1977).

Males Compete with Each Other for Control over the Resources Females Want

Reproduction is cheaper for males and is limited primarily by access to mates. It is in the male’s interest to have multiple mates, and males can improve their reproductive success by controlling access to the resources that benefit females. Ideally, the more a male can monopolize access to resources, the more they can monopolize mating opportunities. This can lead to intense direct competition over resource control and the evolution of polygynous mating systems (one male mates with multiple females).

Gaining access to mates through resources is contingent on the defensibility of the resources. That is, the benefits of monopolizing resources must exceed the costs of defending them. The spatial and temporal distribution of resources is an important influence on resource defensibility. Resources are difficult to defend when they are evenly distributed or ephemeral. But the more resources are clumped in space and/or time, the greater their potential to be the subject of intra-male competition (Emlen and Oring 1977).

Males can gain status as an outcome of intra-sexual competition, providing them with priority access to resources. This can make high-status males more valuable to females. But status can

also limit female choice when high-status males have priority access to fertile females.

Males that are less directly competitive can gain access to females using mating strategies that don't involve resource control, such as sneaking. Females can benefit from mating with such males through indirect benefits, like increasing the genetic quality or variance of their offspring (Reichard et al. 2007).

The Institution of Resource-Defense Polygyny

A mating system describes who mates with whom. They develop as females and males act to maximize their fitness interests over resources and mates in a given context. Humans inhabit a wide variety of environments and express a diversity of social systems. Accordingly, humans display a variety of mating systems – from monogamy (one male/one female) to promiscuity (many males/many females).

Monogamy is believed to be the ancestral state due to the costs and benefits of foraging for resources. Provisioning offspring through foraging requires parents to cooperate (i.e., hunting and gathering), and resources are seldom economically defensible. However, farms and livestock are economically defensible resources that intensify male-male competition for their control. Males can also produce these resources with less dependence on cooperation from females. This coerces females into dependency on males for resource access. Males with more resources can accumulate multiple mates under these ecological conditions, which can ecologically or socially institute resource-defense polygyny (one male/many females). Other factors, including cultural norms (e.g., rules against polygamy) and the operational sex ratio (sexually active males/fertile females), also shape the resultant mating institution (Hartung et al. 1982; Kaplan et al. 2009).

Females in Polygynous Bonds Can Compete with Each Other

It is the male's interest to accumulate multiple mates because this increases his reproductive

success. However, it is in the female interest to limit resource competitors because this allows her to invest more in her offspring's quality. Females can achieve these fitness aims by selecting males that have fewer partners and influencing the selection of future partners. Females can also benefit by cooperating with a mate's other partners in childcare and resource exploitation, but only if this increases the gains of resource production (e.g., shared labor duties). Females can also form dominance hierarchies and benefit from the presence of subordinates (Mulder 1992).

Mother's Use Resources to Improve Their Children's Reproductive Success

Within a mating system based on resource control, wealthy males can improve reproductive success by having many mates and hence many children. However, female reproductive rate is limited by time and not the number of mates. Thus, females improve their own (inclusive) reproductive success by investing in the quality and reproductive success of their descendants. In this sense, female strategies to compete for resources often play out over multiple generations. The result is that competition between females over resources can more closely resemble a conflict of family lineages, as opposed to the individualistic and overt conflicts between males over mates (Stockley and Bro-Jørgensen 2011).

Reproductive success in males rich with resources can be many times greater than males with meager resources. Female reproductive success, by contrast, is less variable (even the most reproductive mother is limited by gestation time). However, female inclusive fitness may become more variable with successive generations. This is because mothers with very successful sons can achieve greater reproductive success than mothers with unmated sons. Thus, it is in the female interest to improve the reproductive quality of her sons with maternal investments and resource inheritance. Mothers can also reduce the competitive burdens on their polygynous

daughters by providing them with resources. Finally, females can inhibit the reproduction of other females, so as to ensure better resource access for their own children (Hartung et al. 1982; Mulder 1992; Stockley and Bro-Jørgensen 2011).

Conclusion

Females use aggression, social positioning, and reproductive inhibition to secure resources for themselves and their descendants. Males can gain access to fertile females by monopolizing these resources, thereby instituting female selection (and competition) for males based on both genetic and resource quality. However, the form and consequences of competition depend on the defensibility of the desired resources. Resources are easier to secure and defend when they are clumped in space and/or time, and this allows males to monopolize mates by monopolizing resources.

Ancestral humans relied on indefensible foraged resources and mostly had socially monogamous mating systems. However, crops and livestock are defendable resources that can lead to the evolution of “resource-defense polygyny.” In these systems, males with more resources can accumulate more mates, but females maintain an interest to reduce competition from other females.

Regardless of the mating system, females act to improve their inclusive fitness by using resources to improve their descendants’ reproductive quality. This multigenerational competition of lineages can be expressed in maternal resource investments, inheritance patterns, and inhibitions on the reproduction of others. When male reproductive success depends on resource quality, females can improve their inclusive fitness by investing in the resource quality of their sons. Similarly, mothers can provide resources to their daughters to reduce their competitive strain.

Definition

Humor as “nonserious social incongruity” has four prominent components: a cognitive, emotional, behavioral, and social one.

Introduction

Definitions of humor have changed considerably through the ages, and more recent attempts toward defining the term encompass a multitude of perspectives and are expanding quickly. Thus, definitions of humor either cover only distinct aspects of this multifaceted phenomenon or provide a broad framework for what is called an “umbrella-term” (Ruch 1998, p. 6). The definition proposed by Martin and Ford (2018) is an example of a rather comprehensive one, capturing the processes involved in the experience of humor:

Humor is a broad, multifaceted term that represents anything that people say or do that others perceive as funny and tends to make them laugh, as well as the mental processes that go into both creating and perceiving such an amusing stimulus, and also the emotional response of mirth involved in the enjoyment of it. (Martin and Ford 2018, p. 3; emphasis in original)

There are several components in this definition, which are (a) a cognitive aspect: the mental processes accompanying both the creation and the perception of humor; (b) an affective aspect: the emotional response of enjoyment (e.g., mirth);

(c) a behavioral aspect: the reaction to humor (laughter); and (d) a social aspect: a communicator and audience (Meyer 2000), also called producer/sender and perceiver/respondent/recipient. These four components cover important perspectives on humor.

Cognitive aspect: Humorous stimuli need to be perceived and processed in order to experience humor. Surprise or “a sudden unexpected change in events” (Gervais and Wilson 2005, p. 399) is fundamental for the initiation of humor. This aspect is also mirrored in script opposition as proposed by semantic and linguistic theories, that is, two sets of conditions are compatible (with a text) but the two conditions are contradictory (Attardo and Raskin 1991). The perception of incongruity is also the basis for major theoretical and empirical research endeavors.

Emotional aspect: Enjoyment or a state of amusement is a key ingredient of humor experiences and, thus, a defining feature of humor. Something has to be perceived as funny and elicit an emotional response such as mirth.

Behavioral aspect: Laughter as the vocal and physiological expression of humor is neither necessary nor sufficient for a humorous event; nonetheless it is often used synonymously with humor. Also, the extent of this behavioral reaction differs considerably between individuals.

Social aspect: Humor is a social phenomenon occurring in social contexts, based on the evolution of social play (Gervais and Wilson 2005; Martin and Ford 2018; Martineau 1972). Closely related are the functions of humor as lubricant or abrasive (Martineau 1972). In a more differentiated notion, humor functions in communications are, paradoxically, to unify or divide (Meyer 2000).

The causes of humor are very diverse, and most of them arise spontaneously. Accordingly, humor has a multitude of forms, with four broad categories introduced by Martin and Ford (2018) as the so-called performance humor, referring to the production of humor (e.g., sit-coms); jokes (e.g., riddles); spontaneous conversational humor (e.g., irony, teasing); and unintentional humor (e.g., physical or linguistic “accidents”). Also, functions of humor vary. Besides social-

psychological consequences for interpersonal relationships and broader group processes, humor has adaptive cognitive and social benefits for individuals like emotion regulation or coping with stress (Martin and Ford 2018).

Overall, the contemporary definitions of humor conceptualized as state usually include a “nonserious social incongruity” (Gervais and Wilson 2005, p. 399). But there are also approaches focusing on the way people use humor in their lives (e.g., humor styles, Martin et al. 2003), or conceiving humor as a rather stable trait (e.g., sense of humor, Ruch 1998). In the following, the four components of humor will be explained in more detail.

Four Components of Humor

The cognitive-perceptual component. Most humor researchers would agree that the core of humor is the perception of an incongruity (Forabosco 1992; Gervais and Wilson 2005; Scheel and Gockel 2017). Humor refers to a thought, statement, or event that is somehow incongruous or surprising and accompanied by humor cues that signal a nonserious mindset (Mulkay 1988). The essence of the humor process is the divergence from a cognitive model of reference and resolution as cognitive mastery (Forabosco 1992). Incongruity theory is the most widely accepted philosophical theory of humor and can be traced back to Aristotle and Kant. According to incongruity theory, “amusement is the enjoyment of something which clashes with our mental patterns and expectations” (Morreall 1989, p. 1).

To illustrate incongruity, take for example this joke: “Hear about the new restaurant called Karma? There is no menu: You get what you deserve.” When reading the sentence, you as reader activate one schema (in this example, restaurant) to interpret the statement and build logic expectations. The new information (“get what you deserve”) does not confirm the expectation. Instead you need to refer to other schemata (common idioms; Indian religions) to be able to resolve the incongruity. The new interpretation

can then lead to the emotional experience of humor. The awareness of an incongruity between two schemata and the resolution of this incongruity causes one to comprehend humor.

In a humorous mode of thinking, the rules of logic do not apply anymore. A thing can refer both, to a restaurant and not to a restaurant simultaneously (Mulkay 1988). Because this joke appears in a chapter about humor and is labeled as joke, you have probably read it in a nonserious mindset, interpreted it as funny, and experienced positive emotions.

The cognitive-perceptual experience of humor is based on characteristics of the humor stimulus and on the social context in which it occurs. First, the humor stimulus leads to the perception of an incongruity. Second, the comprehension of this incongruity occurs in a nonserious mindset (Martin and Ford 2018). The perception of incongruity in a nonserious mindset seems to be typical for all forms of humor that are mentioned above: performance humor, jokes, spontaneous conversational humor, and unintentional humor (Martin and Ford 2018).

The concept of incongruity offers a valuable basis for empirical research. Martin (1998) concluded in his review that there is considerable evidence for a close relationship between the ability to create humor and creative abilities. The creation and resolution of incongruence can even be regarded as creativity.

The emotional component. Positive emotions are widely considered to be among the consequences of humor. This assumption has received ample empirical support (e.g., Abel and Maxwell 2002; Szabo 2003; Tagalidou et al. 2018). However, the specific kind of emotion that is associated with the experience of humor is difficult to identify because this emotion is closely related to the humorous “aha-moment,” that is, the cognitive component of humor, and with laughter, that is, the behavioral component of humor. Martin and Ford (2018) suggest that the distinctive emotion accompanying the experience of humor is *mirth*. It is “gladness or gaiety as shown by or accompanied with laughter” (according to the Merriam-Webster dictionary). Mirth clearly denotes an emotion that is distinct from the

cognitive and behavioral component of humor and that can vary in intensity from mild to strong. Another suggestion for the specific emotion associated with humor is *exhilaration* (Ruch 1993). This word is related to *hilarity*, which means cheerfulness.

Empirical research about the emotional component has mostly focused on positive affect in general rather than specific emotions such as mirth. Participants who watched a humorous (as compared to non-humorous) video reported higher levels in positive affect – independent of participant gender, experienced stress, and trait humor (Abel and Maxwell 2002). In another study, participants reported their well-being after exercising, watching a humorous video, and watching a documentary (Szabo 2003). Humor and exercise increased positive well-being. A similar pattern of results was found in a test of a 7-week humor training in a subclinical sample (i.e., individuals with stress-related and other burdening symptoms; Tagalidou et al. 2018). Participants reported higher levels in cheerfulness immediately after the training and at follow-up one month later.

In interpersonal humor exchanges, the positive emotion can spread from one person to another (Attardo 2019). Speakers of humorous comments usually signal their humorous intent by using behavioral clues such as smiling or laughing. Because listeners often have a tendency to unconsciously imitate the behavior of their conversation partner (Chartrand and Lakin 2013), recipients of humorous comments should also smile or laugh – independent of their humor appreciation. They should therefore experience positive emotions because one’s facial expression directly influences one’s emotional experience (facial feedback hypothesis). This spread of positive emotions from one person to another can explain why and how humor is often followed by more humor in conversations.

Functional magnetic resonance imaging (fMRI) studies have identified key factors that are involved in the cognitive and emotional components of humor. This technique measures blood flow in the brain and can therefore identify the brain areas associated with particular tasks and

situations. Study results indicate that both components are associated with the activation of different, but connected areas of the brain (Shibata et al. 2014). Reading a punch line in a humor condition of an experiment elicited greater activation in the regions associated with comprehension and with the experience of positive emotions (Shibata et al. 2014). Another fMRI study (Amir et al. 2015) showed that humorous interpretation was associated with more brain activation than non-humorous interpretation. Participants first saw ambiguous drawings and then received a suitable caption leading to either a non-humorous or a humorous interpretation. After a humorous interpretation, more brain activity in the areas of the brain associated with the connection of remote concepts and with unexpected rewards was observed. Thus, the emotional experience of humor could be the result of combining remote ideas that lead to an unexpected activation in reward areas. This process is probably mediated by neurotransmitter activity.

The behavioral component. As the vocal-behavioral component of humor, laughter is the outward manifestation of mirth. Laughter has a distinctive “sonic signature,” which is “characterized by stereotyped features of note structure, note duration, inter-note interval and a decrescendo” (Provine and Yong 1991, p. 121). This vocalization is distributed species-wide and thus easily recognized (Provine and Yong 1991).

The intensity of laughter ranges from faint smiles to outbursts of guffaws. At high intensities, the whole body may visibly be involved, as indicated by reddened skin, bodily movements like rocking the body or throwing back the head, etc. (Martin and Ford 2018).

Also, the process of laughing has distinguishable (prototypical) components: First, the mouth widens and its corners are pulled up (like when smiling) (Berlyne 1972). An “unusual respiratory pattern, accompanied by vocalization” (Berlyne 1972, p. 51) is the second component. According to Fry (1994), this “stimulatory phase” is accompanied by an increase in physiological activities like heart rate, blood pressure, blood circulation, and pulmonary ventilation. Also, “skeletal muscles are exercised; the brain experiences

electrochemical activity” (Fry 1994, p. 114), thus, alertness rises, pain perception decreases, hormone production is stimulated, and the effectiveness of circulating immune substance increases (Fry 1994). Overall, these phenomena align with the arousal theory of humor (Berlyne 1972). Two further prototypical components, according to Berlyne (1972), are an opening of the mouth, bared teeth, a grin and a snarl, followed by a generalized tremor, sometimes up to convulsion. In the refractory or relaxation phase following laughter, the psychophysiological system “rewinds”, though all its elements do not reset at the same rate (e.g., immune system is resetting somewhat slower) (Fry 1994).

Laughter depends on motivational and emotional states as well as the social context (Martin and Ford 2018). When laughter is caused by humor, it is usually associated with pleasant affective states (e.g., mirth, exhilaration). However, there is humor without laughter, and laughter without humor. “Humor can be enjoyed without laughter” (Berlyne 1972, p. 51), eliciting far more discreet reactions like smiling. Also, sometimes humor fails. Besides humor, however, there are other causes for laughter including, for example, neurological disorders (e.g., Provine 2000), laughing gas, or tickling. Also, laughter may be provoked by triumph, contempt, and relief (Berlyne 1972).

Whether laughter is genuine or a smile is “faked” is indicated by is indicated by unique facial muscular movements. The so-called Duchenne display appears when both the lip corners are pulled backwards and upwards and the cheeks are raised in a way that causes eye wrinkles (Ruch and Ekman 2001). Put more technically, the joint contraction of zygomatic major and orbicularis oculi muscles indicates an “enjoyment” smile. The Duchenne smile is difficult to fake and thus seen as a reliable indicator of humorous emotions (Hurley et al. 2011). The importance of verifying the authenticity of a smile and the accompanying emotion becomes apparent when considering the interpersonal functions of laughter as stated by evolutionary theory.

Laughter is said to have important evolutionary functions as it communicates emotions.

According to Gervais and Wilson (2005), the Duchenne laughter serves as a “medium for playful emotional contagion” (p. 396). The fact that laughing is an inherited behavior (as indicated, e.g., by the ability of children who are born deaf and blind to laugh, Gervais and Wilson 2005; Provine 2000) supports evolutionary theories of humor. Also, the so-called play-face of higher primates (i.e., relaxed open-mouth face, Gervais and Wilson 2005) may resemble the origins of human laughter and occurs in similar social contexts (e.g., play, Martin and Ford 2018). Tickling of higher primates elicits a behavior “identified as paroxysmal, primarily expiratory, breathy respiration – much like human laughter” (Fry 1994, p. 113). Not only higher primates, but also rather tiny mammals seem to enjoy tickling. Findings from neuroscience indicate that rats “laugh” (Panksepp and Burgdorf 2003), that is, produce an ultrasonic vocalization pattern (50-kHz chirps) when tickled. Believed to indicate positive affect related to joy and social play, this sound may resemble primitive human laughter.

The social component. The experience of humor is strongly influenced by its social context. As mentioned above, humor can affect the emotional experiences of both sender and receiver. The wheel model of humor (Robert and Wilbanks 2012) highlights how humor and affect can spread in groups. A so-called humor wheel starts when people use and perceive humor and experience the resulting positive affect. The expression of positive affect through verbal and nonverbal cues such as laughter can spread from person to person through imitation or emotion contagion (Chartrand and Lakin 2013). This results in all people experiencing positive emotions in that situation, and thus, humor can evolve into a cyclical process. When a speaker says something humorous, listeners regard this as funny, experience positive emotions, and display their emotions by laughing. Positive affect can then bounce back to the speaker. In this way, humorous comments are likely to lead to even more humorous comments. According to the wheel model of humor, humor events have a cumulative impact. In other words, even minor events such as one humorous

comment can have a large impact in combination with other minor events.

The broaden-and-build theory of positive emotions (Fredrickson 1998) can explain the positive social consequences of humor. It postulates that positive emotions “broaden people’s momentary thought-action repertoires and build their enduring personal resources” (Fredrickson 1998, p. 219). In other words, positive emotions that arise due to humor can change individual cognition by broadening the scope of attention, cognition, and action. More importantly in this regard, positive emotions can help to create and maintain social bonds with others as a personal resource. When people share their positive emotions in humorous exchanges by smiling and laughing, they can strengthen their social ties with others (Fredrickson 1998). Similarly, the context of social play in children and apes – demonstrated by laughter or play-face – allows for playful interactions in a safe frame (Gervais and Wilson 2005).

However, humor does not only have positive social consequences in interactions. Robinson and Smith-Lovin (2001) developed a theory of humor and status in groups that predicts, among other things, when and how humor can strengthen or undermine social bonds in a group. Humor can strengthen social bonds, when the humorous comments refer to the group as a whole or to outsiders. Likewise, humor can undermine social bonds when humorous comments refer to one’s self or to another member of the group. This theory therefore highlights the duality of humor. Humor may on the one hand be used for identification (of communicators with their audiences) or clarification (of issues or positions); on the other hand, humor can be used for differentiation (of communicators from others) or enforcement (of norms in a delicate way) (Meyer 2000). Overall, the differentiation function of humor aligns with superiority or disparagement theories of humor (LaFave et al. 1976). According to these theories, individuals experience humor when they perceive another person’s shortcomings. Humor therefore helps to establish or maintain feelings of control, which, in turn, are pleasurable.

Four processes describe why friendly humor impacts social bonds (Cooper 2008). The first

process *affect reinforcement* means that humor can increase positive mood in social interactions. As mentioned above, friendly humor and laughing together create or reinforce positive affect. Second, *perceived similarity* means that humor can lead the sender and receiver to see themselves as similar because they both find the same thing funny. Third, *self-disclosure* refers to the expression of one's own attitudes and characteristics through humor. Finally, *hierarchical salience* highlights the fact that who uses humor and who reacts to it in what manner indicate sender and receiver status in a group.

Conclusion

Humor as a “nonserious social incongruity” has four prominent components: a cognitive, emotional, behavioral, and social one. Humor refers to a thought, statement, or event that is somehow incongruous or surprising and accompanied by humor cues that signal a nonserious mindset. Positive emotions are widely considered to be among the consequences of humor. The distinctive emotion accompanying the experience of humor is *mirth*. The behavioral expression of the humor experience is laughter, which is composed of a unique pattern of vocalizations and muscle movements. The main function of humor is to communicate the emotion humor elicits (most often enjoyment) as well as emotional contagion. This is especially important as humor and laughter are inherently social phenomena. Humor can strengthen or undermine social bonds in a group. The four components of humor are closely intertwined and inevitably overlap, hence making humor a challenging, but fascinating phenomenon for research.

Definition

Concealed ovulation is understood as the lack of external signs of ovulation.

Introduction

In many primate species females have visual signals of ovulation and are receptive in relatively short period within a cycle. The fact that in humans there are no such conspicuous signs of ovulation prompted many scientists to consider this trait as an important factor of the hominization process. Being under specific selection pressures, the loss of visual signs of ovulation is also supposed to be a factor that could have driven important evolutionary changes in social and reproductive structure in human phylogeny. The lack of ovulation signs is also frequently linked to the “loss of estrus,” i.e., continuous female receptivity in the whole menstrual cycle. It is often emphasized that both the concealed ovulation and the loss of estrus are uniquely human traits. When first defined, “concealed ovulation” referred mainly to the anogenital visual signs of the fertile phase. Such visible signs in the form of swelling that extends from genitals to the anal region (“sexual skin”) are very pronounced in the fertile phase of the estrus cycle in chimpanzees. The difference between humans and chimpanzee has prompted many hypotheses about possible selection pressures acting on visual ovulation advertisement. The evolutionary adaptation

of concealed ovulation has been postulated to be linked with: (1) the increase of male cooperation within a group, (2) the emergence of monogamy, (3) the increase in paternal investments, (4) the increase in female acquisition of vertebrate proteins from male hunters, (5) the inability of males to attribute paternity, reducing the risk of infanticide by nonpaternal males, (6) the chance to preserve the best mate choice (with the stress on the best genes for an offspring) by females, or (7) to avoid aggression between females. There are, however, also hypotheses according to which concealed ovulation and constant receptivity were just side effects of other morphological or physiological changes in human evolution. For instance, bipedalism could have constituted a strong selection pressure against perineal swelling because the swelling might have disturbed bipedal locomotion. The other physiological hypothesis is that visually concealed ovulation was the consequence of the selection pressure for increased subcutaneous fat-tissue storage in the gluteofemoral region in females (Pawłowski 1999). This means that, according to different scenarios, it could have been either natural or sexual selection that was involved in the loss of visual signs of ovulation. There are, however, still many controversies over the meaning of changes in the level of ovulation disclosure and adaptation of these changes in human evolution (e.g., Haselton and Gildersleeve 2011, 2016; Havlicek et al. 2015).

Controversies on the Changes in Ovulation Signaling in Human Evolution

The chimpanzee and bonobo are our most closely related living species and therefore they are typically used as a model for a putative human ancestor. Since both these species have pronounced swelling of the perineum (“sexual skin”) that signals ovulation, it is assumed that our common ancestor also had the same trait. It is, however, possible that the common ancestor of chimpanzees and humans did not have very conspicuous ovulation. The pronounced “sexual skin” in hominoids might only have emerged a few million years ago, in the common ancestor of chimpanzee

and bonobo. There is no sexual swelling in orangutans and gorillas. The presupposition that human ancestors had at least small sexual swellings and have lost them over the course of evolution seems, however, to have also scientific support. First, it is the cladistic analysis of this feature in primates (Sillén-Tullberg and Möller 1993). A fully developed anogenital swelling is present not only in chimpanzees but also in many species of Cercopithecoidea and in small size in gibbons. Furthermore, its vestiges are also found in the pudendal lip swelling during ovulation in the gorilla and in pregnancy in the orangutan. The periodic estrogen-dependent peripelvic hyperemia (increase in blood flow) that occurs in humans might also be considered a vestige of swelling. The second argument can be long human penis. Penis lengthening took place mainly in primates that have anogenital swelling (e.g., chimpanzee, stump-tailed macaque, mandrill, yellow baboon). The swelling increases the depth of the vagina, and therefore an effective penetration requires a longer penis. In the case of hominines, however, this trait might have been also affected by bipedalism, resulting in the abdominal relocation of the female genitals.

The disappearance of human anogenital swelling is usually explained by sexual selection associated with monogamy and increased paternal investment. The majority of monogamous primates do not have conspicuous visual signs of ovulation. It is hypothesized that males, when they cannot easily determine the fertility of females, are prone to prolong mate-guarding and, thereby, increase the certainty of paternity. There are, however, a few nonhuman primates that have no swelling and live in nonmonogamous systems. The erect posture of hominines also influenced the position of the external female genitals and therefore made anogenital swelling a less visible signal. More importantly, swelling might have disturbed bipedal locomotion. Therefore, the pressure for efficient biomechanics could have constituted strong natural selection against sexual swelling.

Another controversial issue is the uniqueness of losing visual ovulation signals in the human lineage. A number of nonhuman primates lack

any visual signals of ovulation. Phylogenetic analyses indicate that sexual swelling has been independently lost more than once, and those losses did not coincide with a loss of sexual (behavioral) estrus. The fact that females of some species copulate outside their fertile period challenges the notion of the uniqueness of human constant receptivity.

If ovulation would be completely concealed, i.e., with not the slightest cues (morphological, olfactory, or behavioral) of the steroid hormonal fluctuation within the menstrual cycle (MC), sexual intercourse would be almost equally distributed across the cycle (barring during menstruation in particular cultural contexts). This does not seem to be the case even in hygienic, modern Euro-American populations.

A number of studies have shown various subtle changes in a woman's morphology (body and face), smell, and voice across the MC. The question is if they are just by-products of some physiological mechanisms or promoted by selection adaptation for signaling fertility state. It seems that in comparison to very subtle morphological changes, the most pronounced within MC and influencing a partner's sexual drive are olfactory cues. It has been shown that in the fertile phase a woman's scent is more attractive for men (Havlíček et al. 2006; Kuukasjärvi et al. 2004). This indicates that men are able to use olfactory cues to distinguish between ovulating and non-ovulating women and that steroid hormones influence these olfactory cues (no effect for contraceptive pill users has been found). There are also other potential cues of fertility that are perceivable; for example, changes in a woman's voice in the cycle. If the cues of fertility in the cycle are detectable, one should expect sexual behavior fluctuations within a cycle. Studies indicate that in the follicular and ovulation phase of the MC, women tend to masturbate more frequently, more often solicit sexual encounters (hetero and homo), and have more sexual thoughts and fantasies. In these phases, women also use more intensive makeup and dress more provocatively. The fact that they are perceived as more attractive in the fertile phase is also supported by the increase of male-initiated

heterosexual encounters and by the increased tips received by lap dancers in this phase (Miller et al. 2007). However, the results on the frequency of sexual intercourse across the MC are not conclusive. Some studies report that except menstruation phase it is relatively constant and others report that it is uneven (with an increase in the fertile phase). The first, methodological problem is that the results on sexual activity are different when data are collected soon after the events and when they are more distantly retrospective. The other problem is that majority of these studies were conducted in western societies, and inferring evolutionary explanations on the basis of such data is very controversial. This is because sexual signaling and behavior may be influenced by numerous environmental and cultural factors. Human traits evolved in completely different conditions than contemporary ones. Our ancestors did not use clothes and had a lower hygiene level. Furthermore, in warmer climatic conditions (as in Africa, where *Homo* evolved), semiochemical signaling was also stronger.

There are numerous controversies over the potential evolutionary meaning of such subtle and not easily detectable cues. In comparison with nonhuman primates, all mentioned changes within MC related to attractiveness and fertility should not be considered as evolved specifically to “signal” ovulation in humans. According to some (e.g., Thornhill and Gangestad 2008), the subtle cues of peak fertility in humans have not evolved for the purpose of signaling fertility. These cues are just inevitable side effects of estrogen level increase during the follicular and ovulation phases (“leaky cues hypothesis”). They claim that a completely hidden peak of fertility would be most adaptive for women, but the physiological costs of eliminating even the slightest morphological, olfactory, or behavioral cues due to sex hormones fluctuations would be very costly. Although we have abundant evidence indicating that fluctuations of the steroid hormone levels across the MC are related to perceivable cues of fertility, the question remains as to whether

evolutionary pressures promoted maintaining these hormone-related fertility cues or whether for some reasons removing these cues was impossible.

There is also other explanation for why men are able to perceive the shifts in women’s attractiveness and possibly detect their “current” fertility across MC. Since the difference in fertility and estrogens level is quite big between women, men could be rather adapted to discriminate the cues informing about this between-individual variance in sex steroid (reproductive related) hormones. Selection could have acted rather on detecting potential (overall) than on “current” fertility. This is “perceptual spandrel hypothesis” in which men’s benefit gains would be related to the discrimination of fertility between women, and the MC shifts would be just a by-product of men’s general preference for the cues of high estrogens level between women (Havlicek et al. 2015).

Conclusion

The ovulation concealment problem and the potential adaptiveness of the different cues shift across MC are still debatable. We do not even know if the ovulation was visually disclosed in our common ancestor with chimpanzees and therefore, if in our evolution there was strong selection against signaling ovulation. The evidences show that ovulation is not completely concealed (e.g., olfactory cues) in human, but what were evolutionary causes for only very subtle fertility level disclosure within MC is controversial and remain a challenge for the future studies.

Concealed Ovulation and Multi-male Groups

Rebecca L. Burch
State University of New York at Oswego,
Oswego, NY, USA

Definition

Concealed ovulation refers to the loss of ovulatory signals (visual, behavioral, pheromonal) in a species. Research suggests the loss of ovulatory signals occurs most often in multi-male mating

systems and may help maintain monogamous mating systems.

Introduction

Female mammals and other species are normally sexually receptive for only a circumscribed period around the time of ovulation, and both the ovulatory and receptivity period are advertised to males by distinct visual, behavioral, or pheromonal signals (Andelman 1987). Most species possess slight or overt ovulation, showing vulval swelling or reddening, while others have marked sexual swellings including perineal skin (Sillén-Tullberg and Moller 1993). The contrasting pattern of dampened or concealed ovulatory signals accompanied by sexual receptivity outside of the ovulatory period is frequently referred to as concealed ovulation. This is less common and understood (Andelman 1987).

Concealed ovulation does occur within species across the animal kingdom, although overt ovulation is much more prevalent. Typically, the female gives clear signs by pheromonal, morphological, or behavioral signals when she is ovulating and males focus their copulations on that period (Miller 1996). There is some amount of consensus in the literature that mating system and signs of ovulation are strongly correlated, if not involved in a causal relationship (Alexander and Noonan 1979; Hrdy 1979; Burley 1979; Daniels 1983; Turke 1984; Andelman 1987; Steklis and Whiteman 1989). Most of these hypotheses are based on the observation that sexual swellings, the major signal of obvious ovulation, mainly occur in a multi-male breeding system (Hrdy 1981; Hamilton 1984). Sillén-Tullberg and Moller in 1993 conducted a phylogenetic analysis using two behavioral characters; the presence of ovulatory signals and type of mating system (monogamous, multi-male, or uni-male). Through parsimony analysis of characters, Sillén-Tullberg and Moller found it possible to infer ancestral states and character transformations by mapping present-day ovulatory states and mating systems.

Emergence of Concealed Ovulation

Through their analysis of extant taxa, Sillén-Tullberg and Moller (1993) found that ovulatory signs are absent in every type of mating system in the Order Primate. They found that sexual swellings have evolved independently at least three times and the absence of ovulatory signs is inferred to have evolved 8–11 times overall: one to two times in platyrrhini, one to two times in cercopithecini, twice in macaca, one to two times in the Presbytis clade, once in the Colobus clade, and twice in Hominoidea.

In cases where ovulatory signs are inferred to disappear, it occurs many times in a non-monogamous context and at most once in a monogamous one. Sillén-Tullberg and Moller (1993) concluded that in the majority of instances, maybe all, when ovulatory signs have been lost it has been in a non-monogamous context. Sillén-Tullberg and Moller go on to state that of the extant monogamous taxa, none possess sexual swellings and most have no visual ovulatory signs, which would indicate a connection between monogamy and lack of ovulatory signals. According to the authors, monogamy has evolved four to six times in the absence of, and one to three times in the presence of ovulatory signs. The absence of signs is much more tightly coupled with monogamy than with any other mating system. They conclude that the absence of ovulatory signs could be an important, though not necessary, prerequisite for the evolution of monogamy if concealed ovulation evolved first. In the analysis of mating systems, the authors stated that it is often assumed that the ancestral states in our lineages are those of the chimp (multi-male mating systems with pronounced sexual swellings), but Sillén-Tullberg and Moller's parsimony mapping indicated that a multi-male system has evolved independently in the chimpanzee lineage and that the human ancestor was most likely a harem holder.

Mating Systems

A comparison of the phylogenetic analysis of mating systems by Sillén-Tullberg and Moller with the phylogenetic analysis of sexual

promiscuity by Strassmann (1996) showed a high correlation, as would be expected, of mating system and promiscuity. The behavioral ecology literature has long established the relationship between mating systems of species and cultures and their sexual behavior (Hamilton 1984; Stribley et al. 1987; Arnold and Halliday 1992). The multi-male mating system was associated with high promiscuity, while monogamy was associated with low promiscuity. This lends support to Sillén-Tullberg and Moller's (1993) hypothesis. There are slight differences in the phylogenetic trees of the respective studies that could be accounted for by the different experiments and observations analyzed in the respective studies.

Sillén-Tullberg and Moller's analysis was unable to discern which behavior developed first, concealed ovulation or monogamous mating system. Therefore, the questions of exactly how and when these traits occurred or were maintained remain. Even with all the data on extant taxa and analysis of the emergence of concealed ovulation, the subject that pervades the literature is why this trait would emerge or become adaptive.

Adaptiveness of Concealed Ovulation

The most cited hypothesis regarding the evolution and adaptiveness of concealed ovulation was put forth by Alexander and Noonan (1979) that females concealed ovulation as a strategy to obtain male aid in childcare. A female who provided clues to her ovulation would risk losing paternal investment for two reasons. First, her mate would suspect that other males had detected her ovulation. This would lower his confidence of paternity and consequently reduce his willingness to invest in his mate's offspring. Second, a male aware of his mate's ovulation might copulate with her only during that period and spend the remainder of his time seeking to impregnate other females. If he were successful the first female would run the risk that he might invest in the other children and not in her own. Turke (1984) added an important caveat to this and similar hypotheses: "natural selection probably could

not have favored males who increased paternal care until their confidence of paternity passed some threshold. Furthermore, given even high confidence of paternity, selection is expected to have favored promiscuous tendencies over paternal tendencies as long as promiscuity afforded males a high probability of impregnating many females" (p. 38).

Benshoof and Thornhill (1979) suggested that concealment evolved as a means whereby females could escape the consequences of being paired with a less fit male in a marriage system run by males. A female who concealed her ovulation could mate with a more fit male without attracting the attention of her mate and, because she did not signal ovulation, her mate would continue to invest in her offspring, having little reason to doubt his paternity. If the female were lucky, the majority of her children would be the outcome of matings with males who were more fit than her spouse. Freeman and Wong (1995) agree with this hypothesis stating that it is advantageous for females to conceal ovulation from males as it allows them to ensure that they mate with desirable males around their fertile period and gain benefits such as permanent male protection at all times. This hypothesis assumes that the monogamous mating system emerged prior to concealed ovulation. The majority of theoretical literature supports this timeline (Daniels 1983; Freeman and Wong 1995).

Hrdy (1979, 1981) took a different approach and hypothesized that prehomonid females who concealed ovulation and mated with a large number of males confused the issue of paternity and therefore reduced the possibility that her children by one male would be killed by another. Overt ovulation would create uncertainty in the male (if he can detect ovulation so could any other male and they would mate with her as well, eliminating his paternal certainty) and would also induce him to copulate with her during her ovulation and then copulate with others. A female with overt ovulation would then only have a limited amount of time with the male and would not gain any paternal aid. This hypothesis describes a multi-male mating system which is well-documented in primate literature (Schroder

1993; Halliday and Arnold 1987; Arnold and Halliday 1992; Baker et al. 1993; Chism and Rogers 1997) and Hrdy cites several behavioral ecology studies across species, from squirrels to chickens to primates, to support her hypothesis (Hrdy 1979). This hypothesis was not as widely supported by other socio-biologists, primarily because of the unusual amount of control Hrdy theorized females to have over their environment (Bixler 1986).

These studies and hypotheses are now classic in the realm of sociobiology. There have also been recent additions to this controversial topic. Daniels (1983) theorized that concealed ovulation had its origin in strengthening intragroup bonds during an evolutionary period when only reciprocal sharing and extensive cooperation allowed survival. Like other modern hypotheses Daniels assumes that monogamy was established prior to concealed ovulation. She also stated that the survival of an individual was dependent on sharing and cooperation with others, all of which were facilitated by the emergence of intelligence. Because revealing ovulation threatened monogamy, sharing, and cooperation, survival was also threatened. Self-deception became adaptive "so that certain interests could be excluded, such as selfish propagation, while other more critical activities could be attended to such as sharing and monogamy" (Daniels 1983, p.80). This type of hypothesis, the social bonding hypothesis, states that a trait would arise to increase harmony in the group. This implies that natural selection is acting at a level higher than possible. Natural selection molds behavior for reproductive success, not for social integration (Schroder 1993).

Conclusion

Biologists and bio-psychologists have implicated mating systems, increased intelligence, resource collection, and group harmony in the emergence of concealed ovulation (Alexander and Noonan 1979; Burley 1979; Benshoof and Thornhill 1979; Daniels 1983). Some have even implicated endurance running (Spuhler 1979, cited in Gray and

Wolfe 1983; Schroder 1993). None of these theoretical arguments have brought the scientific community any closer to discovering and/or understanding when and how the salient signals of ovulation have disappeared in hominids, or if there were any signals to disappear. The most thorough and revealing research to date was one study containing a phylogenetic analysis (Sillén-Tullberg and Moller 1993). The phylogenetic analysis by Sillén-Tullberg and Moller gained a great deal of insight into primate mating strategies and sexual behavior, searching for evidence of actual mating systems instead of theoretically constructing them. In order to adequately evaluate the various speculations on the loss of estrus or the concealment of ovulation, it is first necessary to collect such data and standardize the needed procedures. Using this data more specific and thorough phylogenetic analyses, observations of homology, and quantitative genetics can be conducted. Only then will research into the origin or extinction of a given behavior yield satisfactory results.

Definition

The inability of members of a species to detect the physiological state in which the females are capable of reproduction.

Introduction

A number of different species such as chimpanzees, rats, and gorillas display behavioral, physiological, or morphological cues that signal female fertility to male members of the species. These overt expressions of fertility are a form of honest signaling, which is observed among many species. Honest signaling is when individuals display their true qualities as a mate. However, not all species signal their reproductive status to potential mates. Instead, some species conceal their fertility status. Until fairly recently, it was believed that such was the case with human females. While humans generally cannot detect ovulation on a conscious level, a number of researchers have studied the effects of ovulation on male and female behavior. The findings of these studies suggest that women do in fact have the ability to subconsciously emit ovulation cues, and that men can subconsciously detect these cues. Such cues can be observed in the scent, voice, physical features, and a change in mate preference and behavior among ovulating women. For these reasons, it is now believed that ovulation is not entirely concealed in humans.

Honest Signaling and Fertility

Ovulation refers to the time during a woman's menstrual cycle in which an egg is released and is able to be fertilized by a male's sperm to create a zygote. In non-human species, this time of fertility is known as the estrus phase of the estrous cycle. According to Domb and Pagel (2001), in many species, males are able to detect fertility in females so that they know which females to mate with and can successfully reproduce their own genes. Many females from nonhuman primate species signal their fertility status through the swelling of genital areas during the estrus phase of the estrous cycle. In such species where fertility is not concealed, intrasexual competition among males increases a female's chance of successfully mating. Some of these cues, such as those seen in wild baboons, additionally signal a female's reproductive value so that males know the amount of mating effort that they should invest in a particular female, which is dependent upon factors such as her age and reproductive viability, and is an example of honest signaling (Domb and Pagel 2001). In addition to the signals seen in morphological features such as periovulatory swellings, other species show changes in their sexual behaviors, which can be seen when an animal is in heat. The time frame in which an individual can reproduce varies on the type of species as well. For example, the estrus phase in gorillas lasts about 3 days, whereas that of chimpanzees is approximately 12 days. Ovulation in human females lasts approximately 1 day; however, sperm can survive 3–5 days inside of the female reproductive tract. Essentially, this means that there is about a 3–5 day window in which copulation may result in pregnancy in human females. Unlike a number of other species, humans engage in copulation on approximately 23 out of the average 28 day cycle as a result of males not being able to detect when females are able to conceive (Marlowe and Berbesque 2012).

Concealed Ovulation in Humans

In the past, researchers have held the belief that ovulation in humans is fully concealed or

undetectable. From an evolutionary perspective, concealing one's ovulation status can be beneficial for female members of a species for a number of reasons. From an evolutionary perspective, female signaling of menstrual periods to males would allow for an estimate of when ovulation is taking place, which decreases the chances of a man being cuckolded and ultimately raising another man's offspring. Additionally, concealed ovulation prevents any one male in a group from dominating and mating with all of the females, due to the fact that the ovulatory period is unknown (Marlowe and Berbesque 2012). Human ovulation has been seen as unique because even women are unaware of their ovulation status. Self-concealment of ovulation is believed to be selected for along with concealed ovulation from conspecifics, despite the advantages of females being aware of their ovulation status, as having more information can lead to more strategic selection of a mate. Even though women generally report not knowing when they are ovulating, some argue that ovulation can be detectable, such as feeling pain when an egg is released, having an increased sex drive, or secreting higher amounts of cervical mucus due to an increase in estrogen (Freeman and Wong 1995).

Given the imbalance of parental investment between human males and females, such that parental investment on the male part is much lower than females, concealed ovulation is believed to have evolved as a result of it being especially beneficial to females. Oftentimes, females face the dilemma of choosing between a mate that possess better genetics to pass on to an offspring and a mate that will provide more resources but lower quality genes. From a Darwinian perspective, concealed ovulation in humans is advantageous for females because it allows them to copulate with mates that have desirable characteristics and good genes during the ovulatory period, while benefiting from protection and resources provided by males at other times of their cycle (Andelman 1987). By engaging in extra-pair copulations without males being able to detect her, a female could potentially be

able to cuckold her mate, or even get resources from multiple males who believe the child might be theirs. Such behavior essentially allows a woman to get the best of both worlds; genes and resources. However, while this may be beneficial for females, it can also create an adaptive problem for males who pursue long-term mating strategies, as they could potentially be devoting their time, energy, and resources to rearing offspring that are not their own. This is why paternal assurance tactics have evolved, as discussed in the section on paternal confusion.

To further examine the hypothesis of concealed ovulation in humans, Marlowe (2004) compared the behaviors of women in modern society and women of the Hadza tribe in Africa, a group of individuals who live a hunter-gatherer lifestyle that is more natural and similar to those of our human ancestors. The findings suggested that there is in fact no major differences between concealed ovulation in women living in westernized society and those living in a pre-westernized society, and that both groups of women were generally unable to distinguish the time period in which they were ovulating. This suggests that concealed evolution is not a result of more modern times and technology, but that it rather evolved during our semi-nomadic years.

Ovulation May Not Be Entirely Concealed in Humans

While humans appear to be one of the unique species who conceals ovulation, numerous researchers have begun to question whether or not ovulation is truly concealed in humans. Recent studies have provided evidence that women actually emit subtle cues that are instinctively picked up by males. In order to study ovulation cues, researchers have looked at the differences between women who are the peak of ovulation and women who are at a different stage of their cycle. The findings of these studies have shown that women near the peak of ovulation display significant behavioral and physiological changes, in addition to changes in mate preferences. Researchers argue that for these reasons, ovulation is

not fully concealed in humans, even if these behavioral and physiological changes are occurring at a subconscious level.

Ovulating women differ in their sexual behavior and the qualities that they look for in a mate. Whereas it is normally known that females prefer resources and social status over physical attractiveness, women who are near ovulation tend to show a preference for men with more masculine facial features and men who are more competitive (Thornhill and Gangestad 2008). Women who are in a relationship additionally show a preference for other men when their partner lacks these characteristics that are associated with increased masculinity near the ovulatory phase. An evolutionary framework would attribute this preference to an unconscious drive to mate with a male who possesses the best genes for survival in one's future offspring.

Research done by Gangestad et al. (2005) and Geher and Kaufman (2013) looked at additional changes in behavior, physical characteristics, and mate preferences in women who were at the peak of ovulation by reviewing the literature at hand. According to the findings, women near the peak of ovulation are more likely to initiate sex with partners, engage in sexual infidelity, be more attracted to the scent of males who were rated as more creative and more symmetrical in physical features, engage in risk-taking behaviors, dress in clothing that is considered more revealing, and be rated by others as having greater symmetry in their own body parts, such as their faces and breasts.

While these findings make it clear that female behavior seems to change in response to the time period of one's ovulatory cycle, research has also been done to study whether or not these subtle cues are picked up by male counterparts. Thornhill et al. (2003) looked at the difference in scent between women who were ovulating and women who were not. In this study, the "stinky T-shirt" paradigm was used to see if there was a difference in the odors emitted by ovulating and nonovulating females. Both groups of women were asked to wear t-shirts to bed for a couple of nights and avoid using any chemical substances that would alter their natural scent. A group of

men were then asked to rate the attractiveness of the smells of each shirt. Overall, t-shirts that had the odor of ovulating women were rated as more attractive. Similarly, Bryant and Haselton (2009) observed the effects of ovulation on the pitch and perceived attractiveness of female voices. The findings indicated that women's voices change in a way such that they are higher in pitch once a woman is near ovulation. Raters also rated women's voices as more attractive during this high-fertility phase of the cycle. Finally, Miller et al. (2007) looked at the differences in tips earned by exotic dancers during different phases of the menstrual cycle. At the end of the study, dancers who were ovulating earned a significantly greater amount in tips than those who were not ovulating and those who were taking contraceptives. The findings supported the idea that women emit signals that they are ovulating and that perhaps more importantly men are able to detect them. Such findings additionally provide evidence to support that men are willing to give more resources to ovulating women, possibly with the underlying drive that giving a woman more resources will increase the chances of her mating with him.

Conclusion

Ovulation cues are often emitted by females in a number of species. This has been effective in signaling when a mate should copulate with a female and the individual qualities of a potential mate. Humans were believed to be a species in which ovulation was concealed, as sexual patterns generally were not believed to change during the ovulatory cycle and no physiological or behavioral cues were believed to be signaled. However, more recent research has provided evidence to support the idea that ovulation is not entirely concealed in humans as researchers have documented physiological and behavioral changes in addition to change in mate preferences in women during the time of ovulation. Men also experience behavioral changes and find certain characteristics of ovulating women to be more attractive. Why concealed ovulation was selected

for in the first place may be explained by the fact that we are not an entirely monogamous species, and an individual female would benefit from extra-pair copulations with males that can provide better genes while staying with a male that can provide for her and her offspring. Concealing ovulation was advantageous for women, yet because men faced increased chances of paternity uncertainty, it is possible that they evolved their own set of mechanisms to detect the subtle hints that females emit during ovulation.

Definition

The process of forming mental structures within which categorical and relational information is stored.

Introduction

Animals live in complex perceptual and, in many cases, social environments, in which they encounter information that must be processed and stored in memory for later use. That information is then organized into units in order to reduce the amount of information that has to be processed, stored, and later recalled; these units are termed “concepts” (Rosch et al. 1976). Concepts are mental representations of information formed during the process of categorization. Through experience with the world, these concepts become more complex connected within themselves and more linked between each other. The links within and between concepts allow for painting a broader picture of the perceptual and social world. As an example, it could be easily reasoned that most, if not all, animal species somehow categorize food and nonfood (i.e., what can be eaten versus what cannot be eaten). The concept formation process starts with the distinctions between those two categories; then links between foods that can be eaten become linked with concepts for where to find those foods, if those foods are mobile (e.g., can run away); and so on. There has been a substantial amount of research done on the process of concept formation in both humans and nonhuman animals (e.g., Roberts and Mazmanian 1988; Rosch et al. 1976); however, no consensus has been reached regarding the mechanisms used by nonhuman animals during the process of concept formation or whether nonhuman animals’ abilities are truly comparable to humans. The following review will discuss research on conceptual understanding in nonhuman animals, emphasizing the framework proposed by Thompson and Oden (2000).

Thompson and Oden’s (2000) Framework

In a review article, Thompson and Oden (2000) discussed evidence of conceptual understanding, specifically in nonhuman primates. The ability to form concepts is both necessary and adaptive for animals in order to assess their environments and items in their environments. The formation of

these concepts, however, varies based on the mechanisms utilized to organize them and the complexity of the relationship between category members. At the most fundamental level, concepts can be formed based on shared perceptual features. Those commonalities can be sensory or physical in nature, for example, all birds being placed into the same category due to the shared features of feathers, beaks, and wings or all bluebirds being placed in the same category because of shared coloration patterns. These shared features can also be functional in nature (e.g., tools being placed in the same category because they all function in a similar manner). Thompson and Oden (2000) suggested another mechanism by which to organize categories as the members being associated or related to one another. This association can be that the items shared time and/or space with each other at some point in the past or present (e.g., a lamp being associated with a table because it is on the table) or it could be that the items are related to each other in some meaningful way (e.g., a cell phone and its charger). However, the ability to make categorical judgments based not on shared features or associative histories but on the conceptual similarity between the items forms the foundation more sophisticated reasoning abilities, such as analogical reasoning. This judgment of the relation-between-relations is argued to be the highest order of concept formation and, according to Thompson and Oden (2000), had only been definitively demonstrated in humans and chimpanzees, specifically symbol-trained chimpanzees, up to that point.

Conceptual Understanding in Nonhuman Animals

Given the above information, what is known about conceptual understanding in nonhuman animals? Broadly speaking, the ease at which nonhuman animals form concepts depends tremendously on the complexity of the concept (e.g., more abstract or necessitating understanding of the relation-between-relations) and the nature of the task they are asked to perform. In addition, with isolated exceptions, most of what is known about concept formation in nonhuman animals is

limited to pigeons and primates. That being said, gaining a full understanding of conceptual ability in nonhuman animals is far from being reached; however, as with all science, it is a process to be refined and expanded as time moves forward.

Same-Different Concepts

There are two main tasks that are utilized by most research on concept formation in nonhuman animals: same-different judgment (SD) tasks and relational match to sample (RMTS) tasks. Other tasks have been used less frequently, such as a two-alternative, forced choice (2AFC) procedure. In most SD tasks, the animals are shown two (or more) items and are to determine if they are the same or different. In some cases, the animals are reinforced for choosing either only same or only different pairs in a go-no go-type response (e.g., only peck/touch the screen if the items shown are different). Cook et al. (1995), however, utilized an altered SD procedure where the pigeon's same or different decision was made via choosing either the food hopper trained to indicate a same choice or the one trained to indicate a different choice. Overall, this task measured animals' ability to understand same-different concepts, which, according to Thompson and Oden (2000), forms the foundation for higher-level concept formation. The ability to make this judgment would facilitate abilities such as individual recognition in social groups and conspecific versus other species identification, both being evolutionarily prudent abilities for survival. However, the ability to judge same versus different can be done almost exclusively using perceptual cues and, in some cases, memorization of test images after repeated presentations (Thompson and Oden 2000). The same argument could be made for the use of 2AFC tasks where a concept must be inferred from repetitive pairings of two images from two different categories (e.g., animals versus nonanimals) with only one of the categories being reinforced (Vonk et al. 2013).

Both pigeons and primates have demonstrated relative success in forming same-different concepts using SD tasks, particularly with visually based object concepts. Cook and colleagues (1995) utilized their modified version of the SD task to investigate pigeons' abilities to

discriminate between uniform (same) or different textured visual displays. The different displays either contained a color difference or a shape difference within the array. The uniform displays all contained the same color or shape within the array. The pigeons demonstrated acquisition of the concepts of sameness or difference as measured by not just acquisition of the original stimuli but transfer and generalization to novel arrays. This idea of demonstrating *transfer* or *generalization* is important to rule out the simple memorization of the correct images as the discriminative cue instead of the understanding of the sameness or difference (Cook et al. 1995). Similar results were demonstrated by pigeons when their ability to make same-different judgments was investigated using textural differences (as seen in Cook et al. 1995), feature differences (contained a mismatching region of features not present in the rest of the array), geometric differences (contained a different geometric shape than the rest of the array), and object differences (contained a different natural object than the rest of the array [e.g., in an array of all the same birds, one different bird would be present]) (Cook et al. 1997). Additionally, Blaisdell and Cook (2005) used a variation of the SD procedure in which both a same two-item array and a different two-item array were presented simultaneously. Some birds were reinforced for choosing the array that depicted two same items, and some birds were reinforced for choosing the array that depicted two different items. Interestingly, the birds appeared to be more sensitive to differences than sameness, but both concepts were acquired successfully (Blaisdell and Cook 2005).

What may be of importance to note for these studies, as will also be seen in the vast majority of concept formation studies with nonhuman animals, is the large number of trials and sessions it takes the animals to reach criterion for acquisition of the concepts. Each session in Cook and colleagues' (1995) study consisted of 60 uniform and 60 different arrays. The birds, on average, took 22.25 sessions to reach criterion on the fastest acquisition phase of the experiment. Yes, the birds *could* form these concepts, but was it something done with *ease*? It would appear that while this task accurately measures their ability to learn

same-different concepts, it may not be measuring the same-different concepts that might be more ecologically and evolutionarily salient to the animals. In addition, the concept of *entropy* also may play an important role in *how* the birds acquired the concepts. Young and Wasserman (1997) described entropy as the level of variability within categories, where categories with no differences within category members have no entropy and categories where there is a greater amount of differences within categories have higher entropy. In most different arrays, there is a higher degree of entropy present than in the same/uniform arrays. Pigeons appear to be sensitive to this level of entropy when the arrays contain more images per array (e.g., 16 images per array). Both Cook and colleagues (1995) and Cook et al. (1997) utilized large arrays, making the different arrays contain more variability than the same arrays. In comparison, Blaisdell and Cook (2005) used two-image arrays, lowering the entropy within the images, but increasing the *perceptual* differences within the arrays, making the difference within the array more visually salient despite the low level of entropy present in the different arrays.

Evidence from nonhuman primates has also demonstrated mixed results in terms of rate of acquisition and impact of entropy on their performance in SD discriminations. Shields et al. (1997) utilized a slightly modified version of the SD task to compare human performance to that of rhesus macaques. The task paired two arrays of dots against each other with varying degrees of density of the dots in each array. In same trials, the dot arrays were of equal density. In different arrays,

the dot arrays varied in density. In addition, the different arrays varied in degree of density difference as well, making some judgments of difference easier to make than others. The humans and monkeys then had to determine if the two dot arrays were the same or different by either moving the cursor (via a joystick) to the images if the two arrays were the same or to the letter D also displayed on the screen if the two arrays were judged as different. Of much interest is that they also allowed the participants to make a third choice, the choice of uncertainty, meaning that they could not tell if the arrays were the same or different. See Fig. 1 for an example of the trial structure for a different trial.

Both humans and monkeys were determined to be able to judge obvious same and obvious different arrays. In addition, both the monkeys and the humans used the uncertainty response only when they appeared to be actually uncertain about the same-different status. As the discriminations became harder to judge, the amount of uncertain responses tended to increase for both humans and monkeys. Entropy, in this case, would be hard to determine as both arrays contained the same image type (dots), just in different densities, but the results do provide evidence that when the same-different judgment is more explicit, monkeys can form those concepts and make the correct decisions (Shield et al. 1997).

Similar results were found when, again, comparing SD judgments in humans and rhesus macaques using single-item comparisons of polygons (Smith et al. 2008). Original prototype polygons were created via a computer program, and then they were distorted to varying degrees from

Concept Formation,

Fig. 1 Example of a different trial configuration for Shield et al. (1997)

the original. In the same trials, the two polygons were identical (regardless of level of distortion); in different trials, the two polygons differed in the degree of distortion between the polygons (slight, moderate, or large disparities between shapes). In this study, the role of entropy appeared to be more clearly evident in human performance, with human judgments of difference showing a steeper increase as the level of entropy increased. The monkeys showed a more gradual increase in judgments of difference as entropy increased (Smith et al. 2008). Overall, these judgments, in addition to those discussed previously with both pigeons and monkeys, generally strengthen Thompson and Oden's (2000) claim that these same-different concepts are rooted in perceptual cues less than conceptual abilities.

Understanding the Relation-Between-Relations

In order to more fully understand the complexity of conceptual abilities in nonhuman animals, researchers began to test their abilities to understand the relation-between-relations, which form the basis for analogical reasoning. It has only been relatively recently that experimenters have attempted to study this ability in nonhuman animals. Premack (1983) suggested that without language (or some other symbol-based communication system) to guide concept formation, animals would be restricted to judgments of same-different relationships. Making judgments of the relation-between-relations would be restricted to humans and apes, specifically symbol-trained apes (in very specific terms, Premack's symbol-trained chimpanzee, Sarah). It should be noted, however, that what is considered a symbol system is not strictly defined. It could be argued that token economy system, where the animal is trained to give the researcher something (e.g., a rock) before it is given something else (e.g., food), is enough of a symbol system to facilitate success in RMTS tasks (Addessi et al. 2007). This "ape-only" assertion was upheld by failed attempts to demonstrate comprehension of RMTS tasks in monkeys (Washburn et al. 1997 as reported in Thompson and Oden 2000). RMTS tasks are a more difficult version of SD

judgment tasks in that they require the subject to make a same or different judgment based on *why* the two images are the same or different from each other, not just if they are perceptually similar/dissimilar. Typically, a sample image is shown first, and then two comparison images are presented, either with the sample image still present (simultaneous presentation) or without the sample images still present (delayed presentation) to add a level of complexity. The task requires the animal to then choose the array that is either the same as or different from the sample array, depending on which concept is being measured. As an example, two arrays could be judged as the same because they both contain a variety of different images *within* each array instead of having the same image within the array. In this way, the two arrays are the same because they both contain various images within the array, not because they are perceptually similar. One must infer, or abstract, the relationship between the two arrays in order to determine if they are the same or different; in other words, they must be able to tell *why* the arrays are the same or different to be successful in matching to the sample (Thompson and Oden 2000).

Supporting the idea that apes are capable of judging higher-order relation-between-relations, Vonk (2003) tested orangutans (*Pongo abelii*) and gorillas (*Gorilla gorilla gorilla*) on their abilities to judge what was termed *second-order relations*. The animals were given two-item arrays in an RMTS task where they first had to demonstrate first-order relations, matching individual items based on identity (same shape and same color), shape (same shape only), and color (same color only). Both species performed at levels significantly above chance and acquired these concepts after relatively little exposure, some in as little as one session (12 trials), which is in sharp contrast to the hundreds and thousands of trials necessary for pigeons, for instance. Interestingly, only the identity matching trials could be done purely based on perceptual cues alone as in both the shape and color matching trials, the animals would have to make same judgments based on a more conceptual-type rule (e.g., same shape despite

being a different color or same color despite being a different shape) (Vonk 2003).

After successful completion of the first-order relation trials, the animals moved on to the second-order relation trials where they were of the same shape or the same color *between* arrays. For instance, the sample could be one blue circle and one yellow circle. The first comparison array could contain one blue triangle and one blue circle, while the other contained a red triangle and a green triangle. The latter choice would be considered the same choice as it contains the same shapes *within* the array as the sample. Both species successfully learned this discrimination, demonstrating the basis for understanding simple RMTS *despite* not being symbol-trained in any way, challenging Premack's (1983) belief in the necessity of some form of symbolic thought to be successful in RMTS tasks (Vonk 2003).

To test Premack's (1983) and Thompson and Oden's (2000) assertions that monkeys were incapable of understanding the relation-between-relations, baboons (*Papio papio*), Old World monkeys, have been tested on RMTS methods and have consistently been found capable of making judgments of the relation-between-relations (e.g., Fagot and Parron 2010; Fagot et al. 2001). However, baboons, like pigeons, appear to be sensitive to the level of entropy present in the arrays. Fagot and colleagues (2001) found that as the level of entropy within the different arrays fell from the highest possible level with 16 images per array to the lowest possible level with only two images per array, the time it took the baboons to learn the discrimination dramatically increased. Like pigeons in SD tasks, hundreds or thousands

of trials take place during the process of animals reaching criterion on these tasks. Indicating that while baboons can, indeed, successfully judge the relation-between-relations, a task once thought limited to humans and chimpanzees, it is an effortful process.

Fagot and Parron (2010) also discussed the impact of how the baboons are processing the stimuli as a possible factor that could impact difficulty in acquisition. In a typical task, the items within the array are spaced apart from each other by a small distance (see Fig. 2 for a hypothetical example).

Baboons (Fagot and Parron 2010), along with pigeons (Cavoto and Cook 2001) and capuchins (Spinozzi et al. 2003), appear to be treating each item in the array as distinct, individual units, making the task of comparing across arrays much more difficult. This finding is especially true if the space between items within the arrays is much larger than in the hypothetical image shown in Fig. 2. Thus, it appears that one other possible hurdle for the aforementioned species is their preference for local processing over global processing of the arrays. If they were looking at the array on the left as one image, they would more clearly be able to identify that the image on the left depicts the relation same (within array) and the image on the right depicts the relation different (within array), thereby allowing for the comparison to the sample image to require less cognitive resources. However, their focus on the images independently requires them to attend to each image individually before making SD judgments. The local processing bias has not gone unchallenged, though. Goto et al. (2004)

Concept Formation, Fig. 2 Hypothetical example of a two-item array RMTS trial with the center star indicating the initial fixation point

compared the abilities of humans and pigeons to classify geometric shapes based on a local feature or on global features. For both species, categorization based on global features was more rapidly acquired, challenging the use of local cues only.

Further evidence suggesting that monkeys are, indeed, capable of conceptualizing the relation-between-relations comes from work done with another Old World monkey species, rhesus macaques (*Macaca mulatta*), and a New World species, capuchins (*Cebus apella*), indicating that they have also been successful in RMTS tasks. Flemming (2010) made two methodological choices that stand out from those previously used in many studies: simple geometric figures as stimuli and gradually *increasing* the entropy within the arrays (from two-item up to six-item arrays) instead of decreasing as the monkeys progressed. Using simple geometric designs was specifically done to eliminate noise from the images commonly seen in clip art style images or complex patterns/geometric shapes. This decision helped to address the possible issue of local versus global processing of the images in the sense that it took out some of the perceptual noise, allowing the animals to more easily focus on the whole array and not just components of the array. Increasing the entropy, instead of decreasing it, as was necessary for the animals as they progressed through the trials worked as a kind of correction procedure or training if they could not understand the task (as demonstrated by failure to reach criterion) with the two-item arrays (Flemming 2010). The animals were only increased in level of entropy if they *failed* to reach criterion on the two-item arrays. It was found that most animals in both species groups rarely needed the increase in entropy in order to learn the discriminations with the two-item arrays.

Flemming (2010) concluded that it is possible that both species, but particularly capuchins, may be less affected by entropy than are baboons and pigeons. Like apes, rhesus macaques may also be more inclined to use global features in combination with local features when making visual classifications than either baboons or pigeons, especially when classifying more complex stimuli (Diamond et al. 2015). It should be mentioned,

however, that while rhesus macaques have demonstrated the ability to successfully complete RMTS tasks, the ease at which this occurs can be affected by outcome contingencies, with differential reward and punishment contingencies being the most successful combination (Flemming et al. 2011). It could be argued that without the proper outcome contingency, the animals' default processing might be to attend to the more perceptual features, hence the large amount of exposure, training, and number of trials typically necessary before criterion is reached in RMTS tasks (Flemming et al. 2011).

Conclusions

Given the above findings, Thompson and Oden (2000) appear to have been incorrect in their assertion that only humans and apes are capable of judging the relation-between-relations. Both Old World and New World monkeys, in addition to nonsymbol-trained apes, have demonstrated at least rudimentary abilities to understand this concept, which is commonly asserted to be the building blocks of analogical thinking. Taking that information into account, however, the impact of symbolic thinking on concept formation and conceptual understanding should not be dismissed. Wolff and Holmes (2011) suggested that one of the many roles that language, or any symbol system, could play is that of an *augmenter*. In this role of language as an augmenter to thought, and by proxy concept formation, symbols (in the case of language, words) act as a foundation upon which concepts can be formed. Having an ability to link symbols with concepts merely acts to help give a basis upon which to build and hold in place (anchor) those concepts. While having a symbol system is not *necessary* to understand more abstract relation-between-relations, it could definitely augment that process, making it less effortful (Wolff and Holmes 2011).

The literature, as a whole, provides a strong case for the argument that nonhuman animals at the minimum have the foundation for more abstract conceptual understating. Researchers are beginning to focus on the mechanisms that

underlie these abilities, including the neural basis of abstraction (Fabre-Thorpe 2003). Understanding these mechanisms will help to further elucidate the evolution of conceptual abilities in humans. It could be possible that humans share the same basic foundation for building and utilizing concepts as many nonhuman animal species, but the addition of more complex strategies (e.g., language) may allow for the greater ease of acquisition and use of abstract conceptual tools in humans as compared to other species (Fabre-Thorpe 2003). Possession of even the building blocks for abstract conceptual understanding could be beneficial in evolutionary terms for survival, allowing for more complex problem solving and analogical reasoning. It is of importance to continue to fill in the gaps in our understanding of not only how concepts are formed by nonhuman animals, but the breadth and complexity of their capacities, in order to gain a more complete understanding of human conceptual abilities. As has been demonstrated with other skills (e.g., tool use), as we gain more knowledge regarding concept formation in nonhuman species, we may discover that the way in which humans and nonhuman animals conceptualize, categorize, and frame the world may be more similar than different.

Concurrent Mate Retention Tactics

Alastair P. C. Davies

Regent's University, London, UK

Lakehead University, Thunder Bay, ON, Canada

Definition

Concurrent mate retention tactics are defined as mate retention tactics that are complementary, such that the use of one tactic supports the use of another.

Introduction: The Taxonomy of Mate Retention

Once an individual secures a long-term mate or romantic partner, the individual has the adaptive problem of retaining the mate. As the word “retain” may be generally defined as “to keep possession or use of”, mate retention tactics might be considered to have as their aim the prevention of a mate from permanently defecting from or abandoning a long-term relationship. Although they do serve this purpose, mate retention tactics can also reduce the likelihood that a long-term mate will commit an infidelity or temporarily defect from a relationship by engaging in extra-pair copulations (EPCs). Mate retention tactics are, therefore, considered to be tactics that serve both purposes (e.g., Buss 1988; Shackelford et al. 2005). It follows that whether a particular mate retention tactic is aimed at preventing a partner from permanently abandoning a long-term relationship or engaging in EPCs depends on the motivation of the individual employing it.

In a seminal article, Buss (1988) devised a taxonomy of mate retention. His classification

included two categories, subsuming six strategies, subsuming 19 tactics, subsuming 104 acts. For instance, the category *Intersexual Manipulations* subsumed strategies including *Negative Inducements* that subsumed tactics including *Threaten Infidelity* that subsumed acts including *He flirted with another woman in front of her*. Incorporating the acts, Buss devised a *Mate Retention Inventory* (MRI) to assess the frequency with which individuals employ the 19 tactics. Subsequently, Buss et al. (2008) developed a short form of the MRI (*MRI-SF*). The *MRI-SF* assesses the frequency with which individuals employ the 19 mate retention tactics but includes only two acts per tactic.

Notwithstanding Buss' (1988) taxonomy, there remains controversy over the classification of mate retention tactics. A notable example concerns whether *mate retention* is synonymous with *mate guarding*. Prior to Buss, taxonomies considered the terms to be synonyms as mate guarding was considered to comprise any tactic employed by an individual to prevent the individual's mate from being fertilized by intrasexual rivals (e.g., Thornhill and Alcock 1983). However, these taxonomies were based on non-humans, notably insects, and the tactics considered included female mimicry, mate plugs, and vibratory signaling; tactics not typically associated with humans.

Buss' (1988) taxonomy was the first to solely consider mate retention tactics used by humans. Unlike previous taxonomies, it subsumed *mate guarding* under *mate retention*. Buss argued that mate guarding may not reasonably be considered to encompass certain tactics of mate retention; "Tactics may be subtle, including dissuading potential competitors, luring one's mate with positive inducements, or even rendering one's mate less attractive or evocative to competitors. These tactics appear to fall outside the category of 'mate guarding' but are accurately subsumed by the category of 'mate retention'" (p. 292). To support his classification, Buss used the term *direct guarding* to differentiate his definition of mate guarding from the broader definition previously associated with the term. Under *direct guarding*, Buss subsumed the following tactics: *Vigilance*, subsuming acts including *He asked his friends to check up on her*;

Concealment of Mate, subsuming acts including *He refused to introduce her to his same-sex friends*; and *Monopolization of mate's time*, subsuming acts including *He insisted that she spend all her spare time with him*. In light of Buss, it may not be reasonable to consider *mate guarding* as a synonym for *mate retention*. Alternatively, there may be value in following Buss and making a distinction between the inclusive term *mate guarding* and the more restrictive term *direct mate guarding*.

Although both sexes wish to prevent a partner from engaging in EPCs, for a man, a partner's engagement in EPCs may lead to him being cuckolded or unknowingly raising the children of other men. For men, therefore, mate retention tactics also serve as anticuckoldry tactics. Not all anticuckoldry tactics, however, are mate retention tactics. Rather, certain anticuckoldry tactics serve only to reduce the likelihood that offspring will result from an EPC in which a partner has already engaged. For instance, Baker and Bellis (1993) found that the greater the length of time that a couple had spent apart since their last copulation, the greater the amount of sperm that men inseminated into their partners. Because the greater the length of time that a couple has spent apart, the greater is the likelihood that the woman will have engaged in EPCs, Baker and Bellis' finding suggests that the aim of depositing a greater amount of sperm is to increase the likelihood that the men's sperm will outcompete any rivals' sperm to fertilize their partners' eggs. Further, Shackelford et al. (2002) investigated if men have evolved psychological adaptations to reduce the likelihood that a partner's EPCs will result in offspring. They found that the greater the proportion of time that men had spent apart from their partners since their last copulation, men reported the following: a greater attraction to their partners, other men found their partners more attractive, and a greater desire to have sex with their partners. Shackelford et al.'s findings suggest that these psychological adaptations serve anticuckoldry purposes by motivating men to, as soon as possible, place their own sperm in competition with any rivals' sperm that may already be in their partners' reproductive tracts. It follows that while men's anticuckoldry tactic of placing as

much sperm as possible in their partners' reproductive tract as soon as possible serves to prevent extra-pair fertilizations, it serves neither to prevent a partner from engaging in EPCs nor to prevent a partner from permanently abandoning a relationship. It, therefore, cannot be considered to be a mate retention tactic.

Concurrent Mate Retention Tactics

Shackelford, Goetz, Guta, and Schmitt (2006) investigated the relationship between the frequency of men's use of the anticuckoldry tactics of mate guarding and in-pair copulations. They labeled as "concurrent," tactics that are complementary such that the use of one tactic supports the use of another. Shackelford et al. stated that there exists a positive correlation between the frequencies of use of concurrent anticuckoldry tactics.

Following Shackelford et al. (2006), the current article defines "concurrent" mate retention tactics as those that are complementary, such that the use of one tactic supports the use of another. It is, therefore, assumed that there is a positive correlation between the frequencies of use of concurrent mate retention tactics.

As the *Key Idea* article for this section outlines, the literature is informative regarding mate retention tactics that are used concurrently, such as men's concurrent employment of intersexual negative inducements, direct guarding, intrasexual negative inducements, and partner insults (Mckibbin et al. 2007). The *Key Idea* article also outlines the literature regarding personality traits that underlie individual differences in the concurrent use of particular mate retention tactics. There may, however, be additional factors that lead particular individuals to employ particular mate retention tactics concurrently. For instance, men who are of substantial physical stature may be especially likely to use the mate retention tactics "intrasexual threats" and "violence against rivals" concurrently. In contrast, men who are not of substantial physical stature may be especially likely to use the mate retention tactics "concealment of mate" and "monopolization of a mate's time." Women who are especially physically attractive may be

especially likely to concurrently employ the mate retention tactics "sexual inducements" and "jealousy induction." In contrast, women who are low on physical attractiveness may be especially likely to use the mate retention tactics "love and care" and "emotional manipulation" concurrently. Future research might assess these speculations by, for each factor, investigating between which mate retention tactics there is a positive correlation in the frequencies of their use. As the intensity with which mate retention tactics are employed has been shown to depend on the relative mate values of partners and the length of a couple's relationship (e.g., Buss and Shackelford 1997), there would be value in future research investigating if those factors moderate the use of mate retention tactics.

Conclusion

The literature on mate retention among humans is relatively new and the only taxonomy existing for it is that provided by Buss (1988). The primary aims of the current article have, therefore, been to clarify the following: the definition of the term *mate retention*, of which tactics mate retention is comprised, and the definition of *concurrent mate retention tactics*. By doing so, it is hoped that the current article will play a part in eliminating inconsistencies between future studies of mate retention and, therefore, lead to an improved understanding of the topic.

Condition-Dependent Mating Tactic

Felipe Nalon Castro

[Condition-dependent variation in mating decisions](#)

Definition

Condition-dependent mating tactics are the differences observed on the typical expected sexual strategy affected by changes in the socio-environmental conditions.

Introduction

Several studies indicate that males and females have different sexual strategies in our species. Evidence indicates that different behavioral patterns have arisen because of the differences observed in the investment that each of the sexes makes in caring for the offspring. However, recent studies have revealed that the mating tactics used by individuals of the same sex are not constant and that part of these intrasexual variations can be explained by specific socioenvironmental conditions. This research addresses the variation observed in the expression of context-dependent mating tactics and shows examples of variation as a function of (1) changes in the operational sex ratio of the population and (2) environmental parasite load and (3) individual mate value in the local mating market.

Sex, Investment and Environment

For sexually reproducing organisms, offspring are a mixture of genes derived from each parent. One

of the indirect consequences of sex is the emergence of differences between males and females, originating from the gametes' specialization and the asymmetry of the costs associated with gametes' production. Due to differences observed, both primary sexual characters and secondary sexual characters evolved. Primary sexual characters are those with reproductive function required, while the secondary ones were modeled by sexual selection to increase success at copulation, such as the tactic used in mating.

According to the parental investment theory proposed by Trivers (1972), the differences in behavioral responses observed between males and females originated in response to the asymmetry of the energy investment that each of the sexes directs reproduction. On mammalian reproduction, females usually show costs associated with internal fertilization, such as placentation, gestation, and lactation. On the other hand, when compared to females, males have lower costs associated with investing energy in the offspring. It is believed that sexual selection favored an increased competition among males in order to increase their reproductive potential by access to a larger number of females, while the selective pressures that directed the adaptations in the females improved the criteria for choosing partners.

The theory of sexual strategies, proposed by Buss and Schmitt (1993), has shed light on the knowledge cited above to explain findings related to human behavior. In accord to the theory, the mating strategies of males and females were selected as a consequence of the different types of adaptive problems faced by our ancestors. The solutions that emerged from our male ancestors had resulted in a sexual strategy of lesser investment before sexual consent, a search for sexual access to a larger number of partners, and a search for partners who exhibit signs of reproductive health, such as high fertility and reproductive value. In the case of female subjects, the theory predicts that solutions originated to address adaptive problems include a more demanding criteria for partner selection and the search for partners willing to commit time, energy, and resources to women and in their children. Based on the theory

of sexual strategies, the expected appetite for relationships with low commitment and short duration is higher for males compared to females, and this would be the strategy typically expected for each sex.

A strategy implies a set of rules for behavior that is expressed by an animal, but it is important to keep in mind that the environment and even the organisms' abilities to cope with environmental challenges can change over time. In this sense, it is worth arguing that flexible strategies in response to signs of the environment or specific situations may represent greater benefits to individuals who have them. The researchers Gangestad and Simpson (2000) used this knowledge and proposed the strategic pluralism theory. According to this theory, sexual strategies would be conditional strategies, in which the sets of rules that individuals possess allow individuals to use different tactics according to environmental conditions. The authors argue that the intrasexual variation in the tactics used for mating is the result of conditional strategies and that variations in tactics were selected in our ancestors of both sexes, to optimize the energy allocation for parental care or mating effort. Context-dependent tactics are manifested in individuals' reactions to changes in the socioenvironmental context, which may affect their ability to reproduce.

Operational Sex Ratio

Operational sex ratio is an important factor in the environment that affects human mating tactics. The concept of the term represents the rate of receptive males per receptive female in a given period in time. The effect of this factor can be observed in contexts in which the number of men and women in a population is unbalanced. In a population in which the number of men exceeds the number of women, the relative value of the female subjects increases, which implies in the increase of the costs associated with the search of a partner by males. With relatively high value in context, females may be more discriminating in partner selection, i.e., they can more freely express the sexual strategy expected for females by imposing higher levels of investment from their partners before consenting to mating.

Conversely, in populations in which the number of women exceeds that of men, the female relative value decreases. In this context, female individuals are not in a position to impose high costs to potential partners, and male individuals can express the typical male strategy, which aims to reduce resource allocation in parental effort compared to resource allocation to mating (Moss and Maner 2016). Evidence of the effect of sexual ratio on the use of sexual strategies was observed in a cross-cultural study involving 48 nations (Schmitt 2005). The study revealed that in cultures where there are more women, the strategies used tend to focus on short-term relationships, through the acceptance of attitudes and behaviors linked to short-term strategies. Schacht and Mulder (2015) also found that male mating effort varies in predictable ways with the adult sex ratio, when men are in low number compared to women, they are more inclined toward short-term relationships.

Parasite Load

Parasites can be considered hostile forces that affect organisms that have long life cycle, affecting the chances of survival and reproduction. In the ancestral environment, it is possible to imagine that this factor can bring risk and uncertainty regarding the allocation of resources in the mating market. If parasite load was an evolutionary challenge faced by our ancestors that endangered reproductive outcomes, it is possible to imagine that sexual preferences, as a result of the expression of sexual strategies, should be sensitive to ecological variations in the prevalence of parasites. Penton-Voak et al. (2004) compared women's preferences in two societies, one with a lower incidence of parasites and another with a higher parasite load in which medical care is less common. The results indicated the tendency of women of the society with higher parasite load to prefer faces of more masculine men in their local populations. The authors argue that women's preferences may be associated with the characteristics of the environment and that environmental cues linked to the prospect of paternal investment may modulate women's decisions in the search for a partner. The prevalence of parasites may

compromise parental investment, since the intrinsic mortality rate may increase (Robson and Kaplan 2003). Hill et al. (2015) developed a study that examined the relationship between cues indicating that the rate of disease is increasing in their environment and women's desire for sexual variety. They found that women with a history of vulnerability to illness respond to the increase on perceived pathogen load by desiring a greater number of novel partners. Evidence shows that ecological variation in the prevalence of parasites can modify sexual preferences and the patterns of involvement in the relationship prior to consent for sexual access, which consequently affects the mating tactics expressed in the population (Gangestad et al. 2006).

Mate Value

In his work on parental investment, Trivers (1972) theorized that the best sexual strategy may depend on the mate's value and the local environment. Buss and Schmitt (1993) also suggested that individual mate value is important in determining sexual strategy; they argued that the higher the mate value, the greater the possibility of expressing the sex-typical strategy, i.e., the strategy that provides the greatest reproductive outcome. If we take the mating market as a biological market (Noë and Hammerstein 1995), it is possible to assume that the attributes that an individual possesses can be used to attract partners and allocate resources of rivals. In this context, the quality of the attributes of an individual can determine the sexual strategy expressed. Several papers support this understanding.

Surbey and Brice (2007) found that men with high self-perceived mate value endorsed casual sexual activity in contrast to committed relationships. On the other hand, Perilloux et al. (2013) found that women who perceived themselves with high mate value (more physically attractive) were more oriented toward short-term mating. Men with a high market value tend to have sex earlier and have more partners (Landolt et al. 1995); in addition, those with broad, muscular shoulders tend to short-term strategies, seeking more partners, engaging earlier in sex, and presenting more copulations out of the relationship (Hughes and

Gallup 2003). For women, one factor that has a strong influence on market value is age, which is related to fertility and reproductive value. Hughes and Gallup (2003) observed that female reproductive behavior may change with the woman's age, presenting a peak of sexual desire before the age of 30 years.

Conclusion

Condition-dependent mating tactics are the differences observed on the typical expected sexual strategy that are affected by factors present in the socioenvironmental conditions. These tactics are present in our species because those individuals who possessed the ability to adjust their mating strategies for local environmental context might had experimented greater reproductive return while allocating energy in parenting or mating. Evidence indicates that our mind is equipped with a set of mating tactics whose expression occurs in response to clues in the socioenvironmental conditions.

Conditioned Response

Christoforos Christoforou
University of Nicosia, Nicosia, Cyprus

Synonyms

Conditioned reflex; Conditioned reflexive response classically conditioned response

Definition

A conditioned response constitutes the product of learning through the acquisition of a new association between a previously neutral stimulus and a biologically relevant stimulus.

Introduction

Reflexive responses appear when an organism comes across stimuli which automatically trigger a reflexive response. For instance, a puff of air to the eye area automatically induces a reflexive response of an eyeblink (Spence 1978). In a scenario in which an originally neutral stimulus is associated with the puff of air, that formerly neutral stimulus turns into a conditioned stimulus and acquires functions that enable it to induce qualitatively similar responses (i.e., conditioned responses) with the reflexive ones (McSweeney and Murphy 2014). That is, in the field of Pavlovian/respondent conditioning, neutral stimuli refer to any stimulus that originally did not induce any particular reactions, yet through repeated pairings with a biologically relevant stimulus, obtain qualitatively similar functions with it. Respectively, responses that are induced by classically conditioned stimuli are referred to as conditioned responses (Schachtman 2011). That is, a conditioned response is formed through the acquisition of an association between a conditioned stimulus that precedes a biologically relevant stimulus. In other words, the key point that differentiates conditioned responses from unconditioned responses is that conditioned responses are the product of learning through the acquisition of new associations between previously neutral stimuli and a biologically relevant stimulus. In contrast, unconditioned responses are induced automatically and naturally by unconditional stimuli, requiring no previous learning (Shanks 1995).

Classic Example

Ivan Petrovich Pavlov came upon with the essential idea of the conditioned response by coincidence. Specifically, I. P. Pavlov was examining the alternations of dogs' saliva and digestive fluid secretion through mouth and stomach while feeding. At some point, during the course of the experimental procedure that I. P. Pavlov set in order to observe the alternations of dogs' saliva and digestive fluid secretion in response to feeding he observed that the subjects' (i.e., dogs) saliva and

digestive fluid were also secreted every time he and his associate arrived at the laboratory (Spence 1978). Consequently, I. P. Pavlov decided to experimentally examine the functional mechanisms and structures that let the dogs to also secrete saliva and digestive fluid in his presence, rather than exclusively to the presence of food in response to which the dogs reflexively secrete saliva and digestive fluid (Shanks 1995).

Specifically, I. P. Pavlov and his associates systematically administered for several times a neutral stimulus (i.e., sound of a bell) to the dogs just before they presented to the dogs their usual food (i.e., meat powder) (Spence 1978). When this trial was conducted numerous times I. P. Pavlov and his associates observed that the dogs were also secreting saliva and digestive fluid when the stimulus of the bell was administered alone, that is, in the absence of the meat powder (Shanks 1995). Ultimately, I. P. Pavlov came to the conclusion that the constant pairings of the sound of the bell and the food across time and space resulted in the formation of an association between the sound of the bell and the food. Specifically, the sound of the bell which at the beginning was a neutral stimulus, a stimulus that does not elicit a particular response, acquired the capacity to elicit a response that is qualitatively similar to the one that the food naturally and automatically elicits. The response of the dogs became classically conditioned and respectively the sound of the bell turned into a conditioned stimulus. Consequently, the new response that was learned as a reaction to the sound of the bell is named conditioned response (Schachtman 2011).

The Process of Acquisition and Its Role on the Functional Qualities of Classically Conditioned Responses

As mentioned above, a classically conditioned response is formed through the acquisition of an association between a formerly neutral stimulus that consistently precedes a biologically relevant stimulus (McSweeney and Murphy 2014). Yet, it must be noted that there are conditioned responses

that could be formed quicker comparatively to other conditioned responses and respectively there are classically conditioned responses of high and low intensity. The functional qualities of a classically conditioned response rely to a high extent on the conditions through which the process of acquisition took place. Specifically, classically conditioned responses are more efficiently developed when conditioned stimuli are presented just before the unconditioned stimuli, a procedure which is termed “delayed conditioning” because the unconditional stimulus is delayed when compared to the presentation of the conditioned stimulus. In contrast, in trials where the conditioned as well as the unconditioned stimuli are presented at the same time the conditioned responses that are induced are of low intensity (Wills 2012).

The Discrepancy Between Unconditioned and Conditioned Responses

I. P. Pavlov proposed through his work on conditioned reflexes that the same response that was elicited by an unconditioned stimulus could also be elicited by a conditioned stimulus through its association with the unconditioned stimulus (McSweeney and Murphy 2014). However, it quickly became clear that conditioned responses are of lower intensity than unconditioned responses. In addition, research related to classical conditioning after I. P. Pavlov’s work has reliably proposed that the unconditioned response and the conditioned response are not the same responses, but they are usually qualitatively similar. Yet, they can be considerably different. Specifically, it has been consistently cited that I. P. Pavlov’s dogs did not confuse the sound of the bell with the meat powder, but they actually responded to the association among the sound of the bell and the meat powder which has consistently been presented right after the sound of the bell (Ramnero and Torneke 2011). In addition, the unconditioned response as well as the conditioned response are not limited to the secretion of saliva and digestive fluid. Specifically, the secretion of saliva and digestive fluid constitutes just a part of a

multifaceted response through which the dog's body is being prepared for obtaining the meat powder (Staddon 2014).

Classical Conditioning and Emotional Functioning

Classical conditioning could be used to gain an insight into the way that a person's emotive experience of the world is developed during childhood. For instance, despite the fact that only certain stimulus could induce fear responses early on in an individual's life, as the person grows up he/she would acquire further associations which will obtain qualitatively similar operations with the ones that an unconditioned stimulus possesses, which would from then on induce classically conditioned fear responses (McSweeney and Murphy 2014). Therefore, through classical conditioning, phenomena acquire new associations with external stimuli such as behaviors of other people, certain environmental conditions, as well as internal stimuli, such as other emotions and interoceptive experiences. For example, a young boy who experiences sadness and is recurrently challenged by a father who is behaving in a manner which induces fear in the boy, via the process of classical conditioning, the father's behaviors could lead the young boy to develop an association between the affects of sadness and fear, and thus every time he feels sadness (conditioned stimulus) a classically conditioned response of fear is induced. In other words, this boy has learned through classical conditioning to experience fear every time he is sad (Thines 1987).

Further Conditioning: Stimulus Generalization and Stimulus Discrimination

In general, organisms have the tendency to exhibit classically conditioned responses to stimuli that have formal similarities with the conditioned stimuli, a phenomenon that is known as stimulus generalization. The converse conditioning operation to stimulus generalization is a process termed

stimulus discrimination. Stimulus discrimination is the capacity to detect and respond to differences between stimuli, that is, the capacity to detect similarities among stimuli (Ramnero and Torneke 2011). The processes of generalization, discrimination, as well as the equilibrium among them, are of vital importance for living beings in order to learn to adapt and survive (Baum 2017). Specifically, in some situations it is of vital importance to exhibit stimulus discrimination and just respond to specific stimuli. For instance, a living being that must assess an area which is full of ice where a discrepancy in the white color shows the degree to which it is safe or dangerous to pass through the ice must have the capacity for stimulus discrimination. However, in other situations, stimulus generalization has higher adaptive and survival significance, such as the case of an organism which is chased by a variety of predators. In such a scenario, this living organism must respond to everything that presents in front of it.

of classically conditioned associations between neutral stimuli and biologically relevant stimuli (unconditioned stimuli). I. P. Pavlov examined various reflexes, yet his most widely known experiments revolved on responses to food (Spence 1978).

Conditioned Stimulus

Christoforos Christoforou
University of Nicosia, Nicosia, Cyprus

Synonyms

Classically conditioned stimulus; Conditional stimulus; Conditioned reflex

Definition

A conditioned stimulus is any stimulus that prior to learning did not induce any particular response. Yet, through the acquisition of an association with a biologically significant stimulus it acquires the ability to induce a response that is qualitatively similar with the one that the biologically significant stimulus induces.

Introduction

Pavlovian and/or classical conditioning is a type of learning that involves the formation of new behavioral responses through the acquisition of new associations. Classical conditioning has been discovered and methodologically described by a Russian physiologist named Ivan Petrovich Pavlov (McSweeney and Murphy 2014). This type of learning is named “conditioning” since its inventor, I. P. Pavlov, used the term conditioned reflex to label and designate the learning outcome. I. P. Pavlov assumed that a new reflexive response can be developed through the acquisition

The Study of the Gastrointestinal System and Its Role on the Concept of Conditioned Stimulus

I. P. Pavlov came upon with the concept of conditioned stimulus accidentally while examining the physiological processes of the gastrointestinal system (McSweeney and Murphy 2014). Specifically, I. P. Pavlov was studying the alternations of dog’s saliva and digestive fluid secretion through their mouth and stomach while feeding. At some point, during the experimental procedure that I. P. Pavlov set to observe the alternations of dogs’ saliva and digestive fluid secretion in response to feeding, he observed that the subjects’ saliva and digestive fluid were also secreted every time he and his associate arrived in the laboratory. Consequently, I. P. Pavlov decided to experimentally examine the mechanisms and the functional structures that let the dogs to also secrete saliva and digestive fluid in his presence rather than exclusively to the presence of food in response to which the dogs reflexively, that is, automatically, secrete saliva and digestive fluid (Spence 1978).

I. P. Pavlov and his associates systematically administered for several times a neutral stimulus (i.e., sound of a bell), a stimulus that originally did not induce any response to the dogs just before they presented to the dogs their usual food which constitutes an unconditioned stimulus that is a stimulus that reflexively induces a response from the dogs. When this trial was conducted numerous times, I. P. Pavlov and his associates observed that the dogs were also secreting saliva and digestive fluid when the previously neutral stimulus of the bell was administered alone, that is, in the absence of the food (Shanks 1995). Specifically, the constant pairings of the sound of

the bell and the food resulted in the formation of a classically conditioned association between the sound of the bell and the food. In other words, the sound of the bell, which at the beginning was a neutral stimulus since it elicited no particular responses, acquired the capacity to elicit a response that is qualitatively similar to the one that the food naturally and automatically elicits. The response of the dogs became classically conditioned and respectively the sound of the bell turned into a conditioned stimulus (Schachtman 2011).

Facilitating Factors

As mentioned above, classical conditioning takes place through the acquisition of an association between a formerly neutral stimulus and a biologically relevant stimulus that is, an unconditioned stimulus (McSweeney & Murphy, 2014). Yet, for a neutral stimulus to turn into a conditioned stimulus, specific conditions are required. Firstly, when the frequency with which a conditioned stimulus is presented with an unconditioned stimulus is augmented, the likelihood that a neutral stimulus would turn into a conditioned stimulus and induce a conditioned response would be also augmented. For instance, if the frequency with which a sound of a bell accompanies the puff of air is consistently augmented, the likelihood that the sound of the bell would acquire the capacity to induce a conditioned response of an eyeblink is also augmented (McSweeney and Murphy 2014).

Secondly, when the conditioned stimuli are constantly presented in trials in which the unconditioned stimuli are also presented, the likelihood that a neutral stimulus would turn into a conditioned stimulus and acquire the capacity to induce a conditioned response would be higher in comparison with a trial in which the unconditioned stimulus presents too in the absence of the conditioned stimulus (Schmajuk 2010). For instance, if the sound of the bell is permanently presented when the dog receives food, the likelihood that the sound of the bell would obtain the ability to induce a classically conditioned response of saliva

and gastric fluid secretion is augmented (Ramnero and Torneke 2011).

Thirdly, the neutral stimulus must always be presented just before the unconditioned stimulus is presented and not the opposite (McSweeney and Murphy 2014). For example, in order for a tone to acquire the capacity of inducing saliva and gastric fluid secretion, the tone must be presented just before or as the food is received. If the tone is presented after the dog has received the food, the tone would never turn into a conditioned stimulus and be able to induce a response of saliva and gastric fluid secretion because there is no functional significance in acquiring such capacity (Shanks 1995). A further factor that facilitates conditioning is the intervening time between the presentation of the conditioned stimuli and the unconditioned stimuli. Specifically, as the intervening time between the presentation of the conditioned stimuli and the unconditioned stimuli is increasing, the likelihood that a neutral stimulus would turn into a conditioned stimulus and be able to induce a conditioned response is decreasing. For example, if a tone is presented, a long time before a dog receives the food, the tone would not acquire the classically conditioned association with the food so that to obtain the capacity to induce a conditioned response of saliva and gastric fluid secretion (McSweeney and Murphy 2014).

Biologically Prepared Learning and Its Role on Conditioned Stimuli

Humans are endowed with a number of reactions to a variety of unconditioned stimulus, yet the responses that people exhibit are more complex than that. In addition, what is termed as neutral stimulus, sometimes is not exactly neutral (Ramnero and Torneke 2011). Specifically, stimuli could be differentiated in their ability to acquire conditioned associations and not all reactions could be induced by a previously neutral stimulus in the same time framework and potency. For example, in order for a sound of a bell to

acquire the capacity to induce an eyeblink, the sound of the bell and the puff of air have to be associated multiple times. In contrast, in order for a formerly neutral stimulus of a certain odor to acquire the capacity to induce a feeling of disgust and dizziness, a person has to experience once or maybe a few more times the association between that specific odor and a vomit for example (Spence 1978).

Further Conditioning: Second-Order Conditioning

Stimuli that have acquired conditioned associations with an unconditioned stimulus and become able to induce conditioned responses could set the ground for further conditioned associations. For example, when a kid experiences fear in the presence of darkness resulting to the darkness being a conditioned stimulus that induce a response of fear, an additional stimulus that is present in the setting of darkness such as specific noises can acquire too qualitatively similar operations with the conditioned stimulus and induce a fear response, despite that these noises did not accompany the stimulus that initially induced the fear response in the dark setting (Ramnero and Torneke 2011). This phenomenon is usually termed as second-order conditioning. Once more, the stimulus of darkness is likewise one that is not so neutral, as humans are biologically predisposed to more easily associate it with fear than other stimuli (McSweeney and Murphy 2014).

Conclusion

Classical conditioning enables environmental components and/or conditions (e.g., neutral stimuli) to acquire a physiological capacity that did not have before. In other words, an environmental component and/or a condition that possessed other functions or none when it turns into a conditioned stimulus acquires a new function, an acquisition that is vital for any species. Specifically, classical conditioning

provides to a living being the chance to alter its behavior and thus increasing its capacity to adapt and survive (Ramnero and Torneke 2011). For example, a kid might jump on a road full of cars, lacking the association between such situations and threat. Nevertheless, the kid possesses a physiological system that responds to specific unconditioned stimuli such as abrupt cries, screams, and violent acts with an unconditioned response of fear. In a plausible scenario where his/her mother or his/her father responds with a loud scream or exhibits a violent act when the kid tries to jump on the road, the road and/or other relevant stimulus would acquire qualitatively similar functions with the unconditioned stimulus of a loud scream, enabling the road and other relevant stimuli from then on (conditioned stimulus) to induce a conditioned response of fear. Therefore, the acquisition of this new association would enable the kid to alter his/her behavior in similar circumstances (e.g., crowded road) (McSweeney and Murphy 2014).

²Department of Psychology, McDaniel College, Westminster, USA

Synonyms

Classical conditioning; Instrumental conditioning; Operant conditioning; Pavlovian conditioning; Respondent conditioning

Definition

Conditioning involves processes related to changing behavior (i.e., learning). Via the association of stimuli with other stimuli or with behaviors, organisms can effectively respond to their changing environment. Respondent and operant conditioning are two primary modes of behavior change.

Introduction

Processes associated with behavior change can be broadly classified in two categories: respondent and operant conditioning. Respondent conditioning involves the association between stimuli and responses such that a previously neutral (i.e., ineffective) stimulus can elicit an involuntary response that prepares the organism for a biologically significant event. Operant conditioning involves the change in the probability of an emitted voluntary response as a function of its consequences.

These processes involve the interplay between a behaving organism and environmental events with the end result of a change in the behavior of that organism. The ability to change behavior as a function of environmental events is an evolved adaptation. It is likely that some associations are

more easily formed than others. For example, Öhman and Mineka (2003) suggested that humans and other primates are particularly sensitive to learning to fear snakes, and Garcia and Koelling (1966) demonstrated that taste aversion learning is most likely to occur when rats experience nausea than when they experience pain. The evolution of the ability to learn is the ultimate adaptation, in that organisms can alter their behavior on a moment-by-moment basis and thus adjust to quickly changing environments. In addition, these adaptations may be further modulated depending on the particular evolutionary histories experienced.

Respondent Conditioning

The process of respondent (or classical or Pavlovian) conditioning involves the association between a biologically relevant stimulus and a reflexive reaction. The basic preparation involves presenting a *neutral stimulus* (NS) prior to the occurrence of a biologically relevant stimulus (the *unconditioned stimulus*, US). The US produces an involuntary response called the *unconditioned response*, UR. The predictive relationship between the NS and the US can cause conditioning to occur such that the previously neutral stimulus (now the *conditioned stimulus* or CS) elicits a response (the *conditioned response*, CR).

The prototypic example of this type of conditioning is the salivation that physiologist Ivan Pavlov was able to elicit in his dogs. In this example, a tone (NS) is paired with food (US), producing salivation (UR). After several tone-food pairings, the tone by itself (CS) produces salivation (CR). If the tone (CS) was presented several times in the absence of the food (US), the salivation response would decay, in a process known as respondent extinction.

Although the early focus of research in respondent conditioning was on the contiguity between the CS and US, later work has shown that conditioning is a much more complex and elegant process. Rescorla (1988) suggested that contiguity is neither necessary nor sufficient for conditioning

to occur. Instead, “information that one stimulus gives about another” (p. 152) is of greater importance. That is, the predictive relationship between the NS and the upcoming US is more important than the temporal relations between these two stimuli. In the blocking preparation, for example, a compound light-and-tone stimulus precedes a US (e.g., electric shock). If animals first experience the light alone as a CS, they will not become conditioned to respond to the tone (Kamin 1968).

Rescorla (1988) noted that respondent conditioning occurs when an organism “is surprised” by the “discrepancy between the actual state of the world and the organism’s representation of that state” (p. 155). Thus, respondent conditioning can occur with a single trial or across multiple pairings. The salience of the stimuli to be conditioned, the temporal relations between environmental events, and the complexity of the historical and immediate environment might all influence conditioning (Kamin 1968). Not only are the individual stimuli important, but so too is the context in which the stimuli are presented.

Rather than being a process that governs simple reflexive responding, Pavlovian conditioning is implicated in the processes associated with motivation and emotion. Additionally, this type of associationism is referenced with respect to the development of drug tolerance, analgesia, and immunosuppression (Rescorla 1988), as well as some of the physiological effects of placebos (Price et al. 2008). The responses that are a product of classical conditioning have potential survival value. Organisms that are able to respond not only to biologically relevant stimuli (i.e., the US) but also to associated stimuli (i.e., the CS) may be more likely to survive than organisms that fail to respond appropriately.

Operant Conditioning

Like respondent conditioning, operant conditioning provides a mechanism by which organisms

can alter their behavior in order to adapt to changing environmental conditions. Operant conditioning involves changing behavior by altering the consequences of voluntary behavior. *Reinforcement* and *punishment* are the two processes by which this occurs. A reinforcer is any consequence that increases the future likelihood of the response that produces it. For example, the behavior of driving at a high rate of speed may be reinforced by the consequence of arriving on time. A punisher is any consequence that decreases the future likelihood of the response that produces it. For example, the behavior of driving at a high rate of speed may be punished by the presentation of a speeding ticket, the associated fine, and insurance rate hike. As these examples suggest, behaviors can be simultaneously influenced by complex contingencies of both reinforcement and punishment.

Reinforcers and punishers (i.e., the consequences that strengthen or weaken behavior) can also be characterized as positive or negative. Positive reinforcers and positive punishers achieve their effect through the addition of a stimulus (e.g., presentation of food can serve as a positive reinforcer for the behavior of asking for food), whereas negative reinforcers and negative punishers achieve their effect through the removal of a stimulus (e.g., the removal of headache can negatively reinforce the behavior of taking medicine).

Several variables can influence the effectiveness of operant consequences. Immediacy is perhaps the most important: consequences are more effective when they immediately follow a response. Reinforcers can also be arranged according to *schedules*, which are simply rules that determine when a reinforcer occurs. Different *schedules of reinforcement* produce different patterns of behavior (cf. Ferster and Skinner 1957). For example, a continuous reinforcement schedule provides a consequence for every correct response, resulting in rapid acquisition. In contrast, intermittent reinforcement schedules (in which some correct responses are not followed by a reinforcer) produce slower acquisition, but

result in responses that are more likely to persist despite periods in which no reinforcement is available. Operant extinction is the process in which the reinforcement for a response is terminated. Initially, *extinction* may result in a temporary burst in responding, but if the reinforcer continues to be withheld, responding will gradually decrease in frequency until responding is eliminated.

Discriminative stimuli (also referred to as an S^D or S+) appear before an operant response and signal that particular contingencies of reinforcement are currently in effect. An operant response, however, is not caused by a discriminative stimulus, but rather the previous consequences of the behavior. A green light, for example, sets the occasion for safe passage through an intersection while driving, but does not cause this behavior.

Some consequences can serve as operant consequences without any previous learning being necessary, and these are referred to as *primary* reinforcers and punishers. For example, food naturally functions as a reinforcer for a hungry organism. Through the application of respondent conditioning, however, previously neutral stimuli can become reinforcers or punishers. For example, a clicker (CS) can be paired with a food reinforcer (US), so that the clicker becomes a *conditioned* reinforcer. Conditioned reinforcers and punishers can then be used as consequences to change behavior in the same way as primary reinforcers and punishers.

Together, the processes involved in operant conditioning allow organisms to successfully navigate their environment. Organisms sensitive to reinforcement and punishment can successfully produce desirable consequences (e.g., attention, food) and avoid aversive stimulation (e.g., pain, cold). Responding under the control of discriminative stimuli allows for efficient behavior, contacting reinforcers, and avoiding punishers. Individuals with a sensitivity to operant conditioning might be more likely to survive in their environment, making it advantageous to the species.

Conclusion

The processes described here, respondent and operant conditioning, are a result of the evolutionary development of species. Skinner (1984) suggested that organisms that are able to change their behavior as a function of environmental events are more likely to survive than organisms that are not sensitive to their environment. Respondent conditioning results in the development of new reflexive behaviors, while operant conditioning results in the development of new voluntary behaviors. Both processes operate simultaneously to generate, alter, and eliminate behavior depending on the conditions present in the environment. Such adaptations may make these organisms more likely to survive and reproduce.

Conditions Required for Evolution of Warfare Adaptations

Anthony C. Lopez
Washington State University, Vancouver, WA,
USA

Definition

Describes the ancestral conditions that could allow for the evolution of adaptations for warfare in humans. The evolution of adaptations for warfare is possible when there are low-cost/high-benefit opportunities for violence, and it is also possible even if violence is costly, as long as fitness benefits can outweigh these costs in particular mating contexts. Additionally, in some species such as humans, the existence of warfare adaptations presumes the existence of a coalitional psychology able to track a broader range of group dynamics. In short, the evolution of adaptations for warfare is possible when reproductive benefits can outweigh the variable costs of violence and when those opportunities can be taken advantage of by an evolved coalitional psychology.

Introduction

Warfare is a prevalent feature of human social interaction. Given its significant and recurrent nature, scholars have sought to explain not only why particular wars are fought but also why humans organize into groups and fight each other in general. Some, such as the anthropologist Margaret Mead, have argued that war is a cultural invention and that it likely developed sometime between the agricultural revolution and the emergence of large sedentary proto-states. These authors claim that our evolutionary history and biological makeup can contribute little or nothing to our understanding of why humans fight. In

other words, historical, not biological, explanations for warfare are needed.

Others, however, have argued that group violence in humans is evolutionarily old and that the origins of collective violence can even be traced back to our chimpanzee ancestors, many millions of years ago (Wrangham 1999; Wilson et al. 2014). These authors further argue that the competitive coalitional nature of human evolutionary history had a unique impact on human psychology. Specifically, they argue that due to the fact that coalitional competition had such a significant and recurrent impact on our ancestors' reproductive success, we should expect to see adaptations in the human brain that enable us to reason adaptively in contexts of coalitional competition and violence. These scholars often refer to such adaptations as "adaptations for warfare."

Labels are useful because they help us categorize, define, and understand concepts and dynamics; however, research on the evolution of warfare is one area in which the labels themselves have been the targets of much dispute. Consequently, many disagreements about whether warfare is evolutionarily old or culturally recent actually hinge on disagreements about what warfare is and how it should be defined.

No consensus exists regarding the definition of terms such as "warfare," but definitional clarity at least allows one to evaluate the logical coherence of an argument on its own terms. Clearly defining terms such as "warfare" means disagreements about what warfare is can be momentarily put aside in order to ask a more specific question: given a particular definition of warfare, is there evidence that this behavioral pattern occurred ancestrally? This means that different definitions of warfare will result in different conclusions about its prevalence ancestrally and, by extension, different conclusions about the existence of adaptations for warfare. A logical implication is that some forms of warfare probably have no evolutionary explanation, while other forms of warfare probably do. In short, the importance of definitions is not to be overstated and is a necessary starting point.

Defining Terms: “Adaptation” and “Warfare”

What is an adaptation? Like the concept of warfare, there is much discussion on what a biological adaptation is, as well as whether adaptations in the brain should be studied in a fundamentally different way than adaptations in other parts of the phenotype (body). Evolutionary psychologists generally reject the proposition that adaptations in the brain (“psychological adaptations”) require different explanations than adaptations found elsewhere in the phenotype. Thus, evolutionary psychologists argue that the design and function of specific adaptations in the brain can be explained in much the same way as the design and function of adaptations in the liver or heart.

The brain is not one singular adaptation, but rather a collection of specialized adaptations that, broadly speaking, function to regulate the complex behavior of the organism. Indeed, a feature that distinguishes organisms that are capable of complex behavior from those that are not is the presence of a complex nervous system and brain. Therefore, the specific adaptations that compose the brain are generally designed to regulate some aspect of behavior by processing information from the organism’s environment in specific ways. This is why some evolutionary psychologists will also refer to psychological adaptations as “information-processing mechanisms.”

The process of natural selection explains the existence and design of biological adaptations (Williams 1966; Maynard Smith 1993). When some heritable trait emerges in a population, it can be favored by natural selection if it has a positive effect on reproductive success and when that effect is recurrent over evolutionary time. Resultant adaptations will tend to have certain characteristics; broadly, their design will represent a specialized solution to some reproductive challenge or opportunity faced by the organism. With some exceptions (e.g., frequency-dependent selection and “drift”), heritable traits that have a positive impact on the organism’s reproductive success over evolutionary time will tend to spread

in the population and become universal or near universal in the population.

As information-processing mechanisms, adaptations in the brain are often designed to produce a range of output (e.g., altered hormone levels) contingent upon a range of input from the environment (e.g., having won or lost a contest). The conditional – or “facultative” – nature of adaptations suggests that if there are adaptations that shape the way humans reason about fighting, then variation in the incidence of fighting across a population will not be evidence that adaptations for fighting are not universal or don’t exist. Rather, it is possible that this variation merely reflects the contingent logic of the universal adaptation.

What is warfare? A voluminous range of definitions of warfare exists, and there is no “right” definition of warfare, only myriad sets of behaviors that can justifiably be referred to as involving violence of some kind among groups. Consequently, much depends on one’s area of interest and expertise. Scholars of modern warfare, such as those who make use of the massive Correlates of War database, will (appropriately) define warfare as “sustained combat, involving organized armed forces, resulting in a minimum of 1000 battle-related fatalities within a 12-month period.” However, if this is our starting point, then the question of whether warfare has evolutionary origins must be “no” since no one would argue that this form of mechanized combat is anything but historically recent and evolutionarily novel.

Consider an alternative definition of war: “relationships in which coalitions of members of a group seek to inflict bodily harm on one or more members of another group” (Bowles 2009; Wrangham and Glowacki 2012). This conceptualization opens up the possibility that “war” is an evolutionarily old human practice, which, in turn, opens up the possibility that adaptations for “warfare” exist. Whether one agrees that this is the correct definition of war is ultimately less important than whether a form of coalitional violence can be identified that *did* exist ancestrally, enabling specific inferences about how

adaptations designed in response to those specific ancestral challenges structure our beliefs and motivations in modern environments.

Conditions for the Evolution of Warfare

Given the above perspective on adaptation, and using the broader definition of war (i.e., Bowles 2009), a specific question can now be asked: what conditions must have held ancestrally in order for natural selection to favor psychological adaptations in humans that guide motivation and behavior in the context of warfare?

Reproductive Benefits

The first condition is simultaneously the least satisfying (due of its general nature) but also the most important. That is, the reproductive benefits of fighting in groups must have outweighed its related costs. This can be difficult to identify in the case of aggression – coalitional or otherwise – because of the significant physical costs involved in violence (Allen and Jones 2014). In other words, it is often easier to see the substantial risks and physical costs of coalitional violence than it is to see the benefits. However, there are two types of costs to consider in the context of violence: somatic costs and reproductive costs.

The somatic costs of violence refer to the physical damage that an individual or group sustains as a direct and immediate consequence of fighting, such as the loss of limb or the loss of life. In contrast, the reproductive costs of warfare refer to the reproductive opportunities lost as a consequence of fighting. In other words, one cannot reproduce if they are dead. An evolutionary analysis of warfare must attend to the question of its reproductive costs and benefits. Specifically, the reproductive benefits of warfare must outweigh the costs of participation in violence.

The fact that warfare can result in loss of life means that the theoretical challenge is to explain what reproductive benefits could make up for the costs of warfare when such costs entail loss of life and by extension a corresponding possibility of lost reproductive opportunities for the individual. There are two pathways by which the

reproductive benefits of collective violence can outweigh these costs. The first pathway intuitively occurs when both the somatic and reproductive costs of warfare are actually quite low relative to the reproductive benefits. The second pathway occurs somewhat counterintuitively when, despite very high somatic costs to the individual, the reproductive benefits of violence are even greater.

Pathway 1: Reproductive benefits of low-risk raiding. Collective violence can evolve in coalitional environments in which low-risk/high-benefit aggressive opportunities exist. When these opportunities exist, selection can favor raiding behavior between coalitions. Such behavior has specific characteristics and is well explained by the imbalance-of-power hypothesis (Wrangham 1999). Absent weaponry, success in aggressive encounters is often determined by relative strength, and thus, all else equal, the greater the size asymmetry between coalitions, the more likely the larger coalition is to prevail at low cost to its members. In combination with the element of surprise, the attacking coalition can virtually guarantee a low-cost, high-benefit outcome.

The low costs of asymmetric warfare for the attacking party are clear. However, what are the benefits? The first benefit is a direct consequence of the violence – the rival coalition loses one or more of its members, which constitutes a relative power loss. In an environment in which coalitions are small to begin with, the loss of even one individual would not be trivial. A loss of coalition strength can result in increased attacks from neighboring coalitions and an inability to defend the territory controlled by the coalition. Thus, not only is the rival coalition weakened, but the winning coalition can also obtain greater territory and with it the resources that it contains – both material and reproductive. The material and reproductive benefits of low-risk raiding have been well studied and measured (Wilson et al. 2014).

This “chimpanzee model” of warfare (Wrangham and Glowacki 2012) is a clear illustration of one set of conditions under which coalitional violence can evolve via natural selection, namely, where low-risk/high-benefit aggressive opportunities exist. This pattern can be seen in humans, although with important differences.

Human raiding, like chimpanzee raiding, occurs by stealth, is increasingly likely as the imbalance of power reaches a ratio of 3:1, and is accompanied by non-negligible material and reproductive benefits such as expanded territory (Johnson and Toft 2014). Unlike chimpanzee raiding, however, human raiding can be somewhat more risky due to the presence of weaponry and the cycles of revenge.

It may be the case that chimpanzee warfare offers a glimpse at the ancient “roots” of human warfare. However, while some aspects of human warfare resemble the chimpanzee model, other aspects do not. In a comprehensive review and comparison of chimpanzee and human warfare, Wrangham and Glowacki (2012) argue that there are two problems with the comparison of chimpanzee and human warfare. First, relations among human coalitions can range from hostile and violent to peaceful and cooperative. Second, human warfare seems to entail greater risks to attackers than the chimpanzee model, which returns us to the initial question of how evolution could explain psychological adaptations that motivate high-risk violence. Each is discussed briefly in turn.

The first problem (i.e., cooperative as well as combative coalitions) is not evidence that human raiding is not motivated by psychological adaptations that operate to seize low-risk/high-benefit aggressive opportunities. Rather, it suggests that this “raiding psychology” is part of an evolved coalitional psychology that is equipped with a broader toolkit of coalitional interaction. To oversimplify, one could say that humans have psychological adaptations not only for coalitional violence but also for inter-coalitional (as well as intra-coalitional) cooperation and alliance. This issue must be put aside and returned to in a subsequent section on coalitional psychology. For now, however, what can be said is that the conditional logic of psychological adaptations for intergroup violence in humans likely operates within a wider or at least different set of variables than it does in chimpanzees, encompassing opportunities for aggression as well as alliance and trade.

The second problem (participation in high-risk violence) must be engaged by careful

reconsideration of the reproductive costs and benefits of coalitional violence. The resolution of this second problem reveals the second pathway by which the reproductive benefits of warfare can outweigh its potentially significant costs.

Pathway 2: Reproductive benefits of high-risk battles. Collective violence can evolve despite the existence of significant somatic costs – even individual death – when reproductive resources in the coalition are subject to zero-sum distribution (Tooby and Cosmides 1988; McDonald et al. 2012; Lopez 2016). To understand this argument, the reproductive success of the gene or suite of genes that would benefit from the risk-taking behavior of its host must be examined.

All biological adaptations arise initially as a consequence of a random genetic mutation that is maintained in a population because of its positive effects on the organism’s ability to reproduce. Taken to the fullest extreme, therefore, Dawkins quips that “a chicken is only an egg’s way for making another egg” (Dawkins 1976). Put simply, natural selection describes the processes whereby a gene arises that has some effect on the body of its host, and when this effect causes more copies of that gene to make it into subsequent generations, this gene is under positive selection. Thus, natural selection can favor maternal altruism in part because a mother’s offspring is likely to share a significant fraction of her own genes (Hamilton 1964). Despite the fact that the “vehicle” in which the gene finds itself absorbs a cost to confer a benefit on another vehicle, the reality is that the genes in one vehicle are able to help copies of themselves in other vehicles. So what appears to be altruism at the level of the organism or “vehicle” is actually selfishness at the level of the gene (Dawkins 1983). This perspective can help to reveal the underlying genetic benefits of what often appear to be somatically costly behaviors, that is, behaviors in which one organism absorbs great personal costs to benefit another.

With this “gene’s eye perspective” it is possible to reexamine the reproductive benefits and somatic costs of warfare, beginning with some assumptions. First, assume a polygynous system in which male parental investment is relatively low and in which the primary limiting factor for

male reproductive success is access to females (Trivers 1972). Second, assume a world of two male coalitions that are roughly equal in size. Third, assume that these coalitions fight, resulting in the death of all males in the losing coalition, as well as the death of every male except for one individual in the winning coalition. Fourth, assume that reproductive resources and opportunities are allocated in a zero-sum fashion within the coalition. This means that the reproductive opportunities lost by the fallen equal the reproductive opportunities gained by the victorious survivors (Tooby and Cosmides 1988), which is made possible by the polygynous nature of the system. The result is that the reproductive benefits to the winning coalition are not diminished by its high mortality, but, rather, are reallocated among the survivor(s). The “last man standing” is therefore able to reap tremendously great reproductive benefits from this instance of coalitional aggression, despite the great somatic costs of the effort.

As Tooby and Cosmides argue, this situation therefore means that natural selection can favor a gene that motivates participation in somatically costly high-risk battles. Even if many individuals die from the effort, the zero-sum allocation of reproductive opportunities within the coalition means that the average fitness payoff to the members of the victorious coalition is not diminished by the death of one or even most of its members, assuming the above conditions are met. And since natural selection operates to favor strategies that are successful *on average* over evolutionary time (i.e., despite individual fitness reversals), a heritable propensity for participation in high-risk battles can spread in the population. Thus, even if the result is occasional death, the on-average reproductive benefits can outweigh serious and even fatal somatic costs to individual coalition members. This may be particularly true when a “veil of ignorance” exists regarding the prebattle distribution of risk among the coalition members.

The Strength and Existence of Selection Pressures. What has been shown is that it is possible for the reproductive benefits of risky battles to outweigh their related costs. The theoretical possibility on its own by no means implies that adaptations for warfare exist or that if they do exist,

they must be explained in this fashion. It is merely to suggest that adaptations for warfare can indeed be explained by natural selection operating at the level of the gene and the individual. The concluding section briefly engages the question of whether natural selection operating at other levels (e.g., the group) can explain the evolution of warfare adaptations.

First, however, a related question arises: given the possible ancestral existence of conditions that would have favored warfare adaptations, how strong must this selection pressure be in order for such adaptations to emerge? Recall that in order for selection to build adaptations, there must be some challenge or opportunity in the environment that is both recurrent and has fitness consequences for the organism. Thus, one common critique against the existence of adaptations for warfare is that even if there may be fitness benefits associated with coalitional violence, such behavior was actually extremely infrequent or even nonexistent ancestrally. In other words, one cannot claim that adaptations exist in response to an environmental event that was rare or nonexistent.

This challenge leads to two questions: (1) Did our ancestors engage in coalitional violence? (2) How frequently did they engage in coalitional violence? Unfortunately, the evidence does not allow a conclusive answer to either of these questions, forcing researchers to engage in methodological triangulation and to make educated guesses about the possibility and prevalence of ancestral coalitional aggression. Direct evidence of warfare, such as fossilized bone indentations, mass graves, and weaponry, is exceedingly rare and ultimately nonexistent as one peers further and further back in time.

Proponents of the evolution of warfare, however, point out that the absence of such evidence is not evidence of the absence of warfare; rather, the absence of direct evidence of warfare is instead the absence of the *instruments* of warfare, not of warfare itself. In that sense, the labeling of such evidence as “direct” is unfortunate and imprecise, since such evidence is actually indirect, not direct. Swords, mass graves, and fortresses, for example, are not requisites for coalitional violence, and

therefore their absence from the fossil record after a certain time period does not allow us to conclude that ancestral warfare was nonexistent. As Leblanc and Register wryly note: “The world was hardly peaceful until someone in China or Mesopotamia hammered out the first bronze sword” (2003).

This author has elsewhere engaged the question of the likelihood of ancestral violence, and it is a debate that has been vigorously argued on all sides (Pinker 2011; Allen and Jones 2014; Lopez 2016). However – and somewhat disappointingly for both sides in the debate – the very strongest claim that can be made regarding the existence of ancestral coalitional violence is that the evidence does not allow us to conclude that it did not exist. What seems clear is that unless it can be concluded (which it cannot) that ancestral coalitional violence was nonexistent, even the infrequent recurrence of coalitional violence could very well have provided enough of a selection pressure to favor adaptations for warfare. As has been well explored elsewhere, what appear to be quantitatively small selection pressures at one point in time can sum to very large impacts over evolutionary time (Dawkins 1986). Thus, claims that chimpanzee coalitional violence is not recurrent enough for selection to favor adaptations for warfare fail both theoretically and empirically. In theory, they underestimate the power of natural selection to operate on even the slightest fitness differentials. Empirically, clear evidence demonstrates that the rate of chimpanzee coalitional violence is sufficient to yield significant reproductive benefits (Wilson et al. 2014).

Coalitional Psychology

The previous section explored the structure of reproductive opportunities that could lead selection to favor the emergence of adaptations for warfare. However, in addition to the existence of opportunities, the right equipment is necessary in order to take advantage of such opportunities. Coalitional aggression is fundamentally a collective action problem, and participation in warfare therefore requires a degree of cognitive design for navigating a host of coalitional challenges. In short, adaptations for warfare presume the

existence of an evolved coalitional psychology that is designed to solve problems relating to the building, maintaining, and enforcement of within- and between-group relationships (Lopez et al. 2011).

The complexity of this task is not to be underestimated and requires cognitive mechanisms that perform a range of tasks, such as the following: identify and punish free riders; respond and yield to leadership; and regulate the distribution of resources. In short, collective action for aggression presumes cognitive machinery that quickly and reliably solves a range of related but distinct n-person challenges.

One characteristic of the inseparable link between the unique challenges of warfare and the broad toolkit of coalitional psychology is the immediate and reliable way in which the former triggers the latter. Experimental research in the lab and in the field has repeatedly and powerfully demonstrated the effect of intergroup conflict on within-group cooperation. Specifically, the prospect or actuality of intergroup violence is sufficient to trigger a host of within-group dynamics such as an increase in the overall level of cooperation, greater desire to reward participants and to see noncooperative individuals punished, as well as the associated emotional displays of within-group solidarity and shame or guilt among bystanders (Gneezy and Fessler 2011).

The effect of intergroup conflict on within-group collective action is twofold. First, warfare operates as an “effect multiplier” by enhancing many of the dynamics necessary for the prosecution of collective action in general, such as punitive sentiment toward free riders. Second, warfare triggers a unique set of psychological mechanisms designed specifically for intergroup competition and aggression, such as the tracking of in-group/out-group membership (Kurzban et al. 2001) and relative coalitional formidability (Parker 1974). These two effects of warfare on collective action dynamics mean that researchers must be careful to distinguish between those adaptations that are uniquely designed for warfare and those that are designed for collective action but triggered in the context of coalitional violence. The two sets of adaptations are necessarily integrated yet distinct.

As one example of the integrated nature of adaptations for collective action and adaptations for warfare, Tooby and Cosmides (1988) outline the “risk contract of war,” which outlines the psychological conditions that must be met in order for coalitional violence to be initiated against an out-group. The risk contract consists of two broad components: first, regulation of the individual’s decision to participate and, second, the enforcement of the agreement (or risk contract) on others. The individual decision of whether to participate is regulated by variables such as formidability, the degree of perceived risk, and its expected distribution within the group, as well as the expected distribution of spoils antebellum. The enforcement of the risk contract on others depends on an individual’s ability and willingness to pay costs to reward and/or punish others for the sake of labor recruitment and alliance maintenance. Thus, while the main challenge of the first component is one’s own willingness to participate, the main challenge of the second component is to manipulate the willingness of others.

In short, adaptations for warfare presume the existence of an evolved coalitional psychology that enables solutions to the complex coordination problems posed by intergroup violence. Taken together with the previous section, the overall discussion so far has explored the evolutionary feasibility of both low- and high-risk coalitional aggression, the power of even weak selection pressures to build complex adaptations for warfare, and the role of coalitional psychology for facilitating intergroup violence.

Auxiliary Observations Regarding the Uniqueness of Human Warfare

The above discussion outlines some general conditions that make the evolution of warfare adaptations possible. These conditions alone do not explain or attempt to describe the full range of psychological adaptations that possibly exist in humans for engaging in coalitional violence. Doing so would be the next logical step and requires careful adaptationist analysis of specific

reproductive challenges that is beyond the scope of this brief and general inquiry (McDonald et al. 2012; Lopez 2016). Nevertheless, some brief observations should be made that necessarily complement the preceding adaptationist inquiry into warfare.

Research on the evolution of war and its related psychological adaptations should not blind researchers to the very real and powerful “other half” of the story, namely, the evolved human capacity for peace. The existence of adaptations for warfare does not undermine the case for adaptations for cooperation, alliance, or reconciliation. Indeed, the psychology of cooperation and forgiveness among groups is well studied (McCullough 2008). The most fruitful way forward in these respective areas of research (on war and cooperation) is to examine the ebb and flow of motivations and dynamics related to each. For example, when and why do conflicts escalate or deescalate? Such a question can only be answered by acknowledging both the human capacity for violence and the human capacity for cooperation.

Researchers must also carefully examine sex differences in aggression. There is tremendous evidence of reliable and cross-cultural differences in the way males and females reason about and engage in warfare (Van Vugt 2009; McDonald et al. 2012). The theories of sexual selection and parental investment (Trivers 1972) provide a basis upon which to explain the distribution of sex differences within and between species, and these theories have also been used to successfully explain a range of sex differences in humans, particularly regarding individual and coalitional aggression (Van Vugt 2009). Importantly, the evidence does not show that females never fight; rather, the relevant distinction is to be found in the conditions under which males and females fight (Brooks and Valentino 2011; Lopez et al. 2011).

Research Note: The Levels of Selection Problem

The above discussion has focused on the fitness costs and benefits of warfare for individuals and genes. For instance, under certain conditions, genes that code for behavior-regulatory

mechanisms that motivate participation in warfare can spread either because of the associated benefits that accrue to the individual or *despite* significant costs – even death – to the individual. In the latter case, a gene can spread despite costs to the organism when the on-average result is genetic selfishness. This process is known as genetic selection and can result in patterns of behavior as seemingly dissimilar as maternal altruism and battlefield heroism. In the former case, however, a gene can spread simply because it produces direct positive fitness consequence for the organism in which it finds itself. This is known as individual selection and is the more commonly understood level of selection in evolutionary theory.

In addition to genetic and individual level selection, however, it is theoretically possible for a gene to spread in a population because of the benefits it generates for the *group* of organisms in which it finds itself. This is known as group selection. This is significant for the current discussion because warfare can be thought of as a process by which some groups survive and expand while others whither and perish. Warfare is, at least in this superficial sense, a process of group “selection.”

As a rough illustration, if a heritable trait emerges within the individuals of a group that has the effect of making that group more likely to win battles, then these genes would prosper, while alternative genes in the individuals whose group was vanquished would disappear. The result would be that directional change in gene frequencies is driven by its effects on group success, not individual success. This conceptualization led early critics of group selection to claim that this process can only work when there is no migration between groups and when the rate of group extinction is high (Maynard Smith 1976). Later proponents of group selection argued that both early conceptions of group selection and restrictions offered by critics were excessive or imprecise (Sober and Wilson 1999; Nowak et al. 2010). More recently, scholarship has focused on the possibility that the evolution of warfare has occurred via the simultaneous interaction of multiple levels of selection.

Game theoretic evidence has modeled the viability of warfare evolving via group selection

given what is known about the likely prevalence of ancestral intergroup conflict (Choi and Bowles 2007). Nevertheless, critics of group selection continue to make two points in particular. First, the conditions are rare or absent that would be necessary for group selection to build complex adaptations, and modern genetic data are inconsistent with predictions from group selection (Langergraber et al. 2011). Second, although group selectionists argue that behaviors such as “prosociality,” heroism, and other forms of social altruism can only be explained by group selection, critics argue that these are adequately – and more parsimoniously – explained by natural selection operating at the individual or genetic level (Williams 1966; Price 2012).

Conclusion

The foregoing discussion is an attempt to outline a set of conditions that may facilitate the evolution of adaptations for certain forms of intergroup violence. After defining the relevant terms, this effort consists of several components. First, it is necessary to carefully identify the reproductive costs and benefits of fighting and to identify the conditions under which the benefits of warfare would have outweighed its related costs. Second, if current or subsequent research can demonstrate that these conditions held ancestrally, then support is greater for the possibility that some features of human warfare can be explained as products of human adaptations for intergroup violence.

Adaptations for warfare can evolve when coalitions are faced with recurrent and reproductively significant opportunities for low-risk/high-benefit violence. Resultant adaptations should carefully monitor relevant variables such as relative coalition size, the element of surprise, and opportunities for escape – the ancestral analogue of the “exit strategy.” Indeed it is known that in chimpanzees such opportunities exist and are reproductively beneficial, and the pattern of raiding behavior conforms to this adaptive conditionality (Wrangham 1999; Wilson et al. 2014). Raiding in humans does not perfectly conform to the chimpanzee model due to the fact that human raiding

can entail higher physical risk to participants, and inter-coalition relationships are characterized by peaceful as well as agonistic relationships.

Adaptations for warfare can also evolve even in the face of steep somatic and reproductive costs, as long as the fitness benefits of coalitional violence are even greater. This is possible in a world in which reproductive resources and opportunities are allocated within the victorious coalition on a zero-sum basis. Although a high-casualty war of attrition between two large coalitions results in sizeable fatalities for both coalitions, the zero-sum allocation of reproductive resources for the winners means that the surviving victors stand to reap tremendous reproductive benefits. When selection is operating at the level of the gene, the result can be adaptations that motivate what appear to be individually irrational and even reckless participation in violent conflict. In other words, selfish genes can motivate risky behaviors in individuals when the reproductive benefits over evolutionary time outweigh the fact that such behavior can occasionally lead to individual death.

Warfare is a collective action problem and therefore presumes the existence of cognitive machinery that enables individuals to solve complex coalitional coordination problems. Thus, in order for warfare to evolve via natural selection, the reproductive benefits must outweigh the related costs of warfare, but individuals must also be able to navigate complex coalitional landscapes in the first place.

In addition to an elaboration of the conditions for the evolution of warfare and the search for ancestral evidence that such conditions existed, future research should continue to dissect the information-processing structure of adaptations designed for warfare by examining the adaptive logic of related motivations such as revenge, intergroup anger and reconciliation, xenophobia, morality and sacred values, and sex differences in aggression. Last, but not least, researchers must continue to develop models of multilevel selection to understand the complex interplay of selection pressures that operate not only at the level of

the gene but also at the level of individuals and groups.

Synonyms

Interbrood conflict; Intra brood conflict; Mother-fetus conflict

Definition

The conflict of interest between parent and offspring that arises as a result of the differences in the optimal level of parental investment from the perspective of the parent and the offspring.

Introduction

L'Innocence, a popular eighteenth-century painting from French artist William-Adolphe Bouguereau, depicts a very young mother holding a sleeping infant affectionately nestled into her bosom. As its title implies, the painting's serene imagery connotes the supposed innocence of infancy, when offspring needs are eagerly fulfilled by mothers with no hint of conflict between parent and child. The notion of interminable harmony between parent and child is, however, wholly detached from the reality of parent-offspring relationships observed in nature. Conflict between parent and offspring is routine. An extreme illustration of this is infanticide – a behavior that is observed in a range of species including humans (Daly and Wilson 1988). From an adaptationist perspective, there should be contextual factors that influence the level of parental investment in any given offspring; not all situations are optimal for one to raise children. For example, young women who have many future opportunities to reproduce are more willing to sacrifice investing in a current child when environmental conditions

are poor. Across cultures, there is indeed a decrease in the rate of infanticide with increasing maternal age (Wilson et al. 1995). Concealed in the tranquility of Bouguereau's painting is the reality that the young mother portrayed is at greater risk of abusing, neglecting, or killing the infant she holds if the circumstances of raising this infant are not favorable (i.e., harsh ecology, low resources, poor infant health).

Why should conflict ever arise between parent and child? The idea of conflict between parent and child might seem, at a cursory glance, counterintuitive. After all, the ability of offspring to survive and eventually reproduce constitutes a parent's reproductive success. This brief review will start with the logic of parent-offspring conflict theory. The focus will then shift to a summary of the empirical work on parent-offspring conflict with a specific focus on the literature on humans. Readers interested in broader discussions of parent-offspring conflict theory are encouraged to read: Godfray (1995), Salmon and Malcolm (2011), and Schomler et al. (2011).

Parent-Offspring Conflict Theory

At the core of Trivers' (1974) original formulation of parent-offspring conflict theory (POCT) is Hamilton's rule, the fundamental formulation of kin selection theory (Hamilton 1964):

$$rB > C$$

This simple expression delineates the conditions under which altruistic behavior (behavior that benefits another individual at a cost to the actor performing it) is expected to be favored by natural selection. When the net benefits (in terms of reproductive fitness) gained by the recipient (B), discounted by the relatedness (r) between the actor and recipient, exceeds the fitness costs to the actor (C), then one can expect the costly action (i.e., altruism) to be performed. The relatedness coefficient (r) can range from 0 to 1. This coefficient, a representation of the probability that any two individuals share the same allele at any given locus, is critically important to POCT. The

relatedness between a parent and offspring is $r = 0.5$: an individual allele present in a parent has a 50 % probability of ending up in any of their given offspring. Parents and their offspring are expected to share the same alleles (across *all* loci) 50 % of the time. Critically, while a parent shares 100 % of its alleles with itself ($r = 1.0$), an individual parent only shares 50 % of its alleles with a given offspring. Herein lies the conflict: the optimal level of parental investment of resources from the parent's perspective differs from the optimal level of investment from the perspective of the offspring.

The intensity of conflict should depend on how much parent and offspring disagree (i.e., the “gap” between the two optima). Individual offspring values the benefits of parental investment twice as highly as their parents. How, then, should resources be allocated among offspring? This is a key adaptive problem that parents are confronted with (and have been confronted with across ancestral development). Resources can include calories (food), time, protection, attention, and anything that imposes a cost on the parent by reducing that parent's future reproductive success (see Bugental et al. (2012) for more examples). Resources are finite; any resource allocated to one offspring come at a cost to other offspring (current or future). All else being equal, mothers should be expected to distribute their investment equally among (current and future) offspring since mothers are equally related to each of their offspring ($r = 0.5$). An individual offspring is perfectly related to itself ($r = 1.0$), but its relatedness with each of its siblings is $r = 0.5$. From the perspective of an individual offspring, each can benefit by receiving a greater portion of investment (relative to its siblings) than parents would prefer to give. Mothers wish to allocate resources evenly, while each of her offspring is motivated to secure a disproportionate amount of the resources for themselves. Any allocation decision that results in a cost to the parent and a benefit to an offspring has the potential to become an arena of within-family conflict.

Models of parent-offspring conflict. These tradeoffs are not explicit calculations of fitness costs and benefits on the part of parent or

offspring. Predictions derived from POC models do not suppose that this conflict over resource allocation need be conscious and POCT does not exclusively refer to observable behavioral conflict. Within the framework of POCT, conflict is defined more broadly as the *conflict of interest* between parent and offspring. Early POC models provided the foundation for researchers to quantify the extent of conflict between parent and offspring. These “battleground models” focused on the opposing fitness interests of parent and offspring and helped explain how conflict might be expected to vary as a function of key environmental characteristics (e.g., resource availability, reproductive potential of offspring) (Godfray 1995). Subsequent models helped scientists form predictions regarding how these conflicts might be best resolved (i.e., who “wins”; when to expect compromises; how compromises deviate from the optima of parent and/or offspring).

POC theory is often framed as a battle over resources between a *single* offspring and its mother. As detailed above, the conflict is also a battle over the division of resources between current and future offspring (i.e., among siblings). Mothers not only seek to preserve resources for their own survival, but (ultimately) they also wish to retain sufficient resources to invest in the survival and reproductive success of additional offspring. POC models that focus more explicitly on sibling-competition fall into two overarching categories: interbrood and intrabrood conflict.

Intrabrood and interbrood conflict. In those species that produce multiple offspring concurrently (e.g., avian species that produce multiple offspring per clutch), *intrabrood* conflict among offspring selects for adaptations that can distort the distribution of resources in early development. Each individual offspring can benefit by skewing investment toward themselves and away from other siblings in the current brood. In such cases, each offspring can appeal directly to parents for a greater share of resources and, in essence, attempt to monopolize resources away from rival siblings who also need these to survive. Despite mothers being equally related to each of the offspring in a given brood, some offspring in the brood will

receive a greater share of investment, while other offspring will receive much less.

While POC in the intrabrood sense focuses on the division of resources among members of a current brood, these models are not appropriate for those species that raise multiple dependent children of different ages. In human families, each offspring competes for investment with current offspring and with future siblings. This *interbrood* conflict applies selection pressure to human parents specifically with regard to mechanisms that influence the total amount of investment supplied across a parent's reproductive career. From this interbrood POC perspective, one can expect that offspring will be selected to force parents to supply resources that the parent would otherwise prefer to withhold for future reproduction. Parents must then be equipped with mechanisms that can facilitate discriminative solicitude (Daly and Wilson 1988) to allow parents to make "informed bets" on a given offspring by assaying a wide range of relevant environmental cues such as the availability of resources and the reproductive value of any given child (detailed in a subsequent section).

Interbrood competition is a substantial source of POC in humans. Humans' families include multiple dependent children of different ages. Older children are competing with younger siblings for resources well before those younger offspring are born. However, due to the extended period of immaturity in humans, the resources that older and younger offspring compete for may not be identical. For example, an offspring in utero does not directly compete with her toddler-aged sibling for their mother's energetic resources (i.e., calories). However, a mother that invests energy toward fetal development does so at a cost to her older child. Her toddler may have benefitted from this additional energy in the form of additional vigilance or protection. In both the intrabrood and interbrood models of POC, conflict is often (ultimately) resolved by a compromise between parent and offspring. Parents will invest slightly more than optimal but still less than what would be optimal for a given offspring.

Life history theory. All organisms are expected to be equipped with adaptations shaped by natural selection that allocate resources optimally (within the constraints of the species) across the lifespan in accord with the specific demands of the environment. Life history theory provides a theoretical foundation from which to explore how parents might allocate resources among competing life tasks and how (and why) allocation strategies may differ across a parent's lifetime. Among the most fundamental tradeoffs that parents face in their lifetime is that of current vs. future reproduction. In viewing POC through the lens of life history theory, one can form specific predictions regarding the timing of reproduction and model the precise costs and benefits of reproduction and parental investment and how these costs and benefits may differ within an individual's lifespan (Schlomer et al. 2011).

Effort put into reproducing now will use resources that cannot be used for future reproduction. Parents face the risk of crossing an investment threshold, above which resources invested into current offspring would have produced greater (fitness) returns if these parents instead had allocated those same resources to future offspring. In terms of the *costs* of current reproduction, life history theory focuses on the factors that predict such costs as reduced offspring quantity, reduced offspring quality, and reduced somatic investment (a parent's own growth and survival). For example, those with a greater probability of reproducing in the future (i.e., an individual at the beginning of their reproductive career) will be expected to withhold resources from current offspring (potentially leading to reduced offspring quality) and thus the greater the potential for POC with current offspring. Thus, the intensity of POC is significantly influenced by life history relevant factors such as a parent's age, resource availability (e.g., calories, social support, time), and the level of harshness or unpredictability (i.e., rates of morbidity and mortality) in the surrounding environment. While the divergence of interests between parent and offspring (as well as between siblings) is omnipresent, the lens of life

history theory allows researchers to predict the shifting parameters of the zone of conflict across a parent's lifespan. Life history theory provides a broader context for POCT and allows scientists to formulate more concrete hypotheses about the influence of specific environmental factors on the intensity of POC.

Factors Influencing the Intensity of POC

From a biological standpoint, all children are important. Offspring are a parent's vehicle for getting genes into the next generation. The quixotic notion of a parent sacrificing one's self for offspring – no matter the cost or the situation – is at odds with the predictions of POCT. Decades of empirical work have uncovered some factors that shape the degree of conflict between parent and child and the stages in life (for both parties) that amplify or dampen the level of POC. These factors often influence the cost-benefit calculation of investing (or not) in a given offspring and can include age of parent, age of offspring, number of offspring, sex of offspring, an offspring's reproductive value, resource availability, and the degrees of relatedness between parent and offspring.

Child reproductive value. According to POCT, parents should discriminate among offspring according to markers of fitness. Fitness refers to the reproductive value of an offspring – the expected reproductive success of that individual. An offspring's fitness can be communicated through cues reliably associated with the probability of surviving and reproducing such as age (discussed below) and markers of the offspring's quality like size, health, and competitive ability. Resources are finite, and natural selection should have favored any mechanism that allowed parents the ability to gauge the probability of a child's expected future reproductive prospects. It is not likely that selection would have favored a mechanism that allocated resources to offspring indiscriminate of reproductive value. Across human ancestral development, a child that is unhealthy

or extremely unlikely to survive would have been a bad investment for a parent to make.

How likely is a child to convert each unit of investment into future reproductive success? This is the critical adaptive problem that parents have faced for millennia. Early cues of offspring quality should be of particular importance to human parents due to the exorbitant needs of neotenuous human infants. Infants who show early cues to low quality (e.g., disability, physical deformity) would have been unlikely to survive (much less reproduce) in the ancestral past. Thus, one expects parental solicitude mechanisms to be sensitive to offspring quality very early in a child's life. Indeed, infants born with severe physical deformities and disabilities are much more likely to be victims of abuse, neglect, and infanticide (Daly and Wilson 1984). Mothers with low resources are particularly at increased risk to abuse or neglect their low reproductive value offspring. Specific to human fathers, there is some indication that they also possess mechanisms sensitive to the reproductive value of young offspring: nonresidential fathers' willingness to provide financial support decreased as signs of early health issues increased (Hofferth and Pinzon 2011).

When resources are in short supply or when a parent's local environment is high in environmental risk, parental investment is more effective when restricted to children more likely to survive. There are special circumstances, however, in which parents may invest *more* resources into needier offspring. Parental investment has opportunity costs. Importantly, investment beyond a certain level results in less improvement in an offspring's potential return (quality) than the previous unit did. It is expected that a parent that possesses ample resources can receive greater fitness returns by allocating more resources to those offspring that need it most (provided that satisfying this greater need does not become deleterious to other offspring). Parents in higher resource environments can be assured greater reliability in their investment returns as parents in this context have greater direct influence on child survival and reproductive success. Prior work has provided

some support for this type of need-based investment strategy. For example, Davis and Todd (1999) conducted a computer simulation (with birds) in which a simple decision rule emerged as the most efficient feeding strategy: if resources are scarce, then feed healthiest chicks first; if resources are abundant, then feed neediest chicks first. Utilizing both experimentally varied levels and naturally occurring differences in parental resources, Bugental and colleagues (see Bugental et al. (2012) for review) found support for this model of investment among humans. Mothers who increased their cognitive-emotional resources (through an intervention) invested disproportionate amounts of resources in their needier children, while mothers that did not have these increased resources biased their investment toward healthier offspring. These researchers went on to demonstrate that maternal participation in this intervention predicted improved health of these “needier” children at older ages – an indication that the potential payoffs of investing in the neediest of offspring (when resources are abundant) can be realized in tangible fitness gains.

Genetic relatedness. POC is predicted to increase in intensity with a lower degree of relatedness between family members (i.e., between parent and child, between siblings). In the majority of mammals, females invest far more in offspring than males do. Due to internal fertilization and gestation, females have a distinct advantage over their mates when it comes to gauging relatedness: a female can always be assured that the offspring she believes to be her own are actually her genetic progeny, while males can never have this same degree of certainty. Males do however invest in children that they securely perceive to be their own. The costs of unwittingly investing in children that are, in reality, not a man’s own are substantial. Males then must be equipped with mechanisms that can alert them to cues of paternity. They must be prepared to invest in children only when such cues are present.

Prior work on human fathers has found support for the existence of cognitive processes that

evaluate offspring relatedness based on facial resemblance (e.g., Alvergne et al. 2010). Similarly, Daly and Wilson (1982) found that spontaneous comments about paternal facial resemblance following the birth of a child came more often from the maternal side (i.e., mothers and maternal grandparents) – potentially an attempt by a female’s family to help secure greater parental investment from her mate. In looking at investment in older children, Anderson et al. (1999) found that stepfathers invested substantially less financial resources in their stepchildren’s college education compared to that invested into biological children. A man’s genetic children were 5.5. times more likely to receive any financial assistance for college. In comparing just those stepchildren and biological children that received money for college, genetic children received much larger sums of money as well (on average, \$15,000 more).

Parents tend to be warmer and are more engaged in childcare activities with biological children than their stepchildren (O’Connor et al. 2006). Children living with one genetic parent and one stepparent are 40 times more likely to be abused than children living with both genetic parents (Daly and Wilson 1988). The rate of infanticide is correspondingly much higher in households where one parent is a stepparent (especially for very young children). These findings support the prediction from POC that a parent should wish to allocate resources preferentially toward children that are genetically their own.

Parent’s age. A parent’s age is expected to influence the degree of conflict between parent and child. Younger parents have more of their reproductive careers ahead of them, and thus, these parents should harbor resources in an attempt to maximize “reproductive success” (crudely, the number of healthy offspring that survive and reproduce). This should especially be the case if conditions for raising a child are suboptimal. Young parents, from an evolutionary perspective, can afford to be more discriminating in which offspring they choose to invest in and when to invest (or not).

Much of the evidence (in humans) has come from the work of Daly and Wilson (1984, 1988). The age of a mother was a significant factor in the likelihood of maternal infanticide. As POCT would predict, these young women (likely to have future opportunities to reproduce) appeared to be more willing to sacrifice a child when environmental conditions were poor (i.e., low resources). There is evidence to support the converse as well: older women were the *least* likely to commit infanticide. These women, closer to the end of their reproductive years, could not afford to pass up the opportunity to invest in their infants. Other work across cultures (e.g., Overpeck et al. 1998) also observed this decrease in the rate of maternal infanticide with increasing maternal age. These findings reflect the shifting costs-benefits of investing in a child as mothers get older. For mothers near the end of their reproductive window, foregoing an opportunity to raise an offspring becomes a much riskier bet.

Offspring age. The level of need from offspring does not remain static across development. In humans, for instance, infants require more time and attention than a child nearing the onset of adolescence. The decline in relative offspring need as children mature and the accompanying increases in the ability of older offspring to more immediately convert investment into fitness returns sets up the prediction that the value of offspring should *increase* as children near reproductive maturity. Older offspring (who have not yet reached sexual maturity) should be more valuable investment prospects than younger offspring.

Over the course of human history, mortality rates have been the most pronounced in early development, and this remains to be the case in developing societies. Volk and Atkinson (2013) estimate that approximately 27 % of infants failed to survive their first year of life and approximately 47.5 % of children failed to survive to puberty in environments that would have been similar to the environments that humans have inhabited through ancestral development. The average adolescent has a higher value than the average infant because so many infants do not even survive to become

adolescents. In Daly and Wilson's (1984) work, one again sees empirical evidence for a prediction from POCT: across cultures, it is the youngest offspring that are the likeliest casualties of murder at the hands of their parents. Infants are at a much higher risk of being killed by family members than any other age group, and the rates of children being killed *by parents* drops dramatically after the first year of life in spite of the finding that teenagers were the most likely to be killed at the hands of *nonrelatives*.

Number of offspring. The total amount of resources that a parent can allocate to offspring is finite, and, expectedly, these resources will be in shorter supply as the number of offspring increases in a given family. In humans, larger family size is indeed related to decreased levels of investment (of time) as parents in larger families were observed to be less involved in childcare activities (Lawson and Mace 2009). As family size increases, one also expects to see the downstream consequences of decreased investment such as smaller offspring size and decreased nutritional status. Larger family sizes are linked to decreased growth and decreased survival in humans (e.g., Hagen et al. 2006). If these developmental outcomes were consistently the result of decreased parental investment, one can predict that current offspring should be resistant to the prospect of a parent adding offspring to the existing family. Sulloway (2007) details some evidence to support this prediction: older children reverted to infant-like behaviors aimed at eliciting larger amounts of investment once a new infant was born.

Gender of offspring. Trivers and Willard (1973), using the logic of POCT, predicted that when one sex has a larger variance in lifetime reproductive success than the other sex and when there's variance between sexes in terms of access to valuable ecological resources, one can predict the context in which one sex would be "preferred" by parents. In humans, women have lower variance in reproductive success than men do. Mothers in poor conditions (i.e., low access to resources) are thus expected to prefer raising

daughters – a “bet” that carries less risk. In sum, parents in good condition will bias their investment toward sons, and parents in poor conditions will bias their investment toward daughters.

Evidence for the “Trivers-Willard effect” has come from historical data across cultures. For example, Bereczkei and Dunbar (1997) found that Hungarian gypsies (of lower status and correspondingly poorer access to resources in comparison to native Hungarians) had many more surviving daughters than sons. These gypsies also spent more time nursing daughters than sons and invested more in education for their daughters than sons.

In situations where possession of resources has a marked influence on male reproductive success, there should be a preference for sons over daughters. Among the affluent castes in India, a clear preference for sons can be observed (Gupta 1987). High caste families with sons that could marry women from any caste (as opposed to high caste women who could only marry from their own caste or higher) were more valuable as these sons had the potential to produce larger returns on parental investment. As a result, sons received a heavier share of investment than daughters. Infanticide among the higher castes was somewhat common before the twentieth century, and the victims were overwhelmingly female – adding support to the biased value of males over females in this specific environment.

Prenatal Parent-Offspring Conflict

The view of pregnancy as a time of agreeable cooperation between mother and fetus is incorrect. Any investment by a mother in an individual fetus’ development comes at a necessary cost to that mother’s ability to invest those same resources in other (existing or future) offspring. Investment in offspring survival and development starts well before offspring are born. It is expected then that POC should also begin at least as early in utero. A fetus’ best interests are served when it can increase maternal investment in utero beyond that of what a mother is selected to provide. A mother’s best interests are served when

investment in a fetus is close to levels in line with those that meet the minimum required for a fetus’ survival (thus leaving a greater share of resources for future fetuses). This conflict of interest over the optimal levels of investment in utero provides an arena for intense POC (Trivers 1974).

Pregnancy is a balance between a fetus’ attempts to procure disproportionate levels of investment from its mother and the countermeasures that a mother will employ to restrict the levels of resources allocated to the fetus (Haig 1993). The chief adaptive problem that a fetus must solve is that of survival in utero. The fetus must survive long enough to reach full term. Estimates of miscarriage vary across time and cultures, but a systematic review from Ammon Avalos et al. (2012) estimate that 11–22 % of pregnant women (from Western, industrialized nations) miscarry in weeks 5 through 20 of gestation. In spite of modern medical technology, early gestation continues to act as a type of sieve, where intense selection on the fetus has led to an audition of sorts where an individual fetus must meet a maternal threshold for quality or risk being eliminated.

Nutritional constraint. Fetal adaptations are designed to elicit large quantities of maternal investment across the full length of pregnancy. Mothers, equipped with adaptations designed to invest into each offspring more prudently, can limit nutrient availability to the fetus. Maternal nutritional constraint is estimated to contribute over 50 % of the variance in birth size (see Gluckman et al. 2005). In environments that are predictable and replete with resources, mother and fetus can resolve some of this conflict over nutritional resources through cooperating with each other (i.e., each can afford to compromise).

In those environments where the availability of resources is uncertain, however, this conflict can be disastrous for the mother and/or fetus. If the fetus survives, the restricted nutritional investment can cause enduring health complications well into adulthood. A deprived prenatal environment might calibrate a fetus to permanently develop a “thrifty phenotype” by being small and insulin resistant through the early postnatal period and into adulthood (Gluckman et al. 2005).

In turn, as an adult, the individual might be well suited to an environment in which nutrient supplies were limited (as their metabolic machinery “fits” with that of a resource-scarce environment). However, this individual would be more likely to be become unhealthy in a nutritionally *rich* environment – a scenario in which the postnatal environment is at a mismatch with the environment predicted from the prenatal period.

Blood glucose. For nonpregnant women, blood glucose levels rise after a meal but return to fasting levels once insulin is introduced from the pancreas. A pregnant woman’s insulin levels and her insulin response after meals remain typical until mid-gestation but rise considerably during the third trimester. It is noteworthy that, around this same time, insulin resistance develops, leading to a more prolonged elevation of blood sugar levels post meal. The high insulin levels combined with increasing insulin resistance in the third trimester appears paradoxical. Why would a mother’s body increase the production of insulin while simultaneously decreasing her body’s ability to utilize that insulin?

The answer comes down to intense POC in utero over nutritional resources. Once a meal is ingested, a mother and her fetus must then decide how to “share” the resultant increase in blood sugar (glucose). A mother can keep most of the blood sugar for herself if she can quickly produce sufficient levels of insulin to guide glucose into her cells (if she can reduce blood sugar levels quickly after eating). The fetus, having a vested interest in preventing maternal monopolization of glucose, can counteract this process by secreting human placental lactogen (HPL) – a hormone that increases maternal resistance to insulin (thereby maintaining elevated blood sugar levels for a longer duration which allows the fetus to acquire more glucose for itself). A mother, in response, can try to counterpunch HPL’s influence by further increasing her own production of insulin. The resulting POC escalation over glucose in the blood can have dire consequences for mothers. The benefits to the fetus (i.e., greater share of glucose obtained, increased birthweight) of increasing maternal blood sugar levels can come at cost to mother’s long-term health. If blood

glucose levels remain elevated, mothers increase their risk of developing gestational diabetes.

Maternal blood exchanges nutrients with fetal blood through the placental barrier. This process becomes another arena for conflict between mother and fetus. If the flow of maternal blood to the placenta is increased (e.g., through increasing maternal blood pressure), the quantity of nutrients allocated toward the fetus would also increase (Haig 1993). Mothers can combat “excessive” allocation of nutrients to the fetus by inducing the constriction of maternal blood vessels. The result of this tug-of-war over nutritional resources increases the risk of fetal-induced maternal hypertension. Chronically high blood pressure during pregnancy – a condition that would benefit the fetus thanks to the increased flow of nutritional resources – can result in preeclampsia, a condition that has the potential to cause permanent damage to a mother’s kidney and liver. In some cases, preeclampsia can lead to eclampsia, a potentially fatal condition. In terms of fetal development, it is clear that, despite a fetus’ reliance on the maternal circulatory system for all its needs, mother and fetus do not have completely overlapping interests.

Weaning Conflict

Following birth, the arena for conflict between mother and child shifts to the quantity of breast milk and the duration of breastfeeding. The duration of breastfeeding and the specific timing of weaning has significant relevance to the developmental outcomes of children.

In primates, it appears that weaning processes coincide with the resumption of mating (Maestripieri 2002). One expects weaning conflict to increase around the time when mothers begin to reallocate investment away from breastfeeding and toward producing new offspring. For example, some primate infants increase nipple solicitation when their mothers resume having fertile ovulatory cycles (Gomendio 1991). This strategy may be interpreted as an attempt by offspring to delay or prevent their mothers from reproducing.

Among the Turkana (of Kenya), conflict around weaning tends to be high when mothers resume sexual relations with their husbands (Gray 1996). Resumption of sexual relations represents a transition point where effort is being diverted away from parenting effort (cessation of breastfeeding) and toward producing additional offspring (renewal of fertile cycles). Young offspring should demonstrate particularly intense protest to the possibility of having their sole food source taken away and resist the addition of siblings to the mix. Haig (2014) proposes that disrupting a mother's sleep (i.e., night waking to suckle) is an adaptation of infants to extend their mothers' postnatal infertility (due to breastfeeding), thus delaying the birth of additional siblings. Breastfeeding suppresses ovarian function, and any adaptation that infants possess that can extend the duration of nursing (even for a few weeks) will be advantageous from the individual offspring's perspective.

Mate Choice

From an evolutionary perspective, parents should have a profound interest in their children's reproductive choices (e.g., *when* to commence mating, *who* to mate with). An offspring's choice of sexual partner and/or long-term mate can have a significant influence on the reproductive success of an entire genetic line for generations to come. Whether a society contains formally arranged marriages or individuals are essentially free to choose who to mate with, parents across cultures demonstrate varying levels of control over their children's mating partners (Apostolou 2011). Parents have their own reproductive interests at heart when evaluating an offspring's mate, but these interests, as mentioned throughout, do not necessarily overlap with offspring interests. The arena of offspring mate choice is one ripe with conflict between parent and child.

Parents may wish for their children to find a mate that complies with their own standards whereas their children will seek out mates that

are more compatible with their own preferences. Some evidence in humans suggests that parents and offspring disagree on timing of marriage, the age of an offspring's partner, and the importance of genetic quality in a mate (Apostolou 2011). While cultural differences do exist, offspring sometimes seek to compromise with their parents on the physical attractiveness, dependability, and family background of their mates. The data suggest that people are more willing to trade off physical attractiveness when selecting a partner for their children compared with a partner for themselves. In a sample of 443 young adults in Japan, parents and children disagreed on the acceptability of mating with a partner that had "poor" genetic quality (i.e., attractiveness, intelligence, creativity) – offspring viewed this as more unacceptable than did their parents (Dubbs et al. 2013). In terms of parental investment potential (e.g., family background, education) and cooperation with the in-group, however, being low on these traits was viewed as more unacceptable by parents than offspring.

Conclusion

The interests of parent and offspring only partially correspond. Natural selection favors adaptations in offspring that can help obtain resources beyond what parents are selected to give. Parents are equipped with mechanisms designed to resist providing resources too far beyond the optimum from their perspective. Whenever a given trait or behavior results in a cost to one party and a benefit to the other, parent and offspring are expected to disagree about the optimal levels of resource allocation. As demonstrated above, there are many arenas that one can expect to see POC. Conflict exists well before offspring are born and persists across the lifespan. Conflict between parent and offspring is ubiquitous across species and cuts across time and culture. The application of POCT to understanding the adaptive functions of specific decisions made by parent and child will be a fruitful area of research for generations to

come. Conflict between parent and offspring goes well beyond the conventionally researched parent-child skirmishes over chores, homework, behavioral problems, dating, or friendships. While the influence of POCT to evolutionary psychology has been pronounced, the impact of POCT to developmental psychology and other disciplines has only recently begun.

Synonyms

Intersexual competition; Interlocus sexual conflict

Definition

A conflict between the evolutionary interests of individuals of the two sexes, mostly related to reproduction.

Introduction

Men and women's interests differ substantially in many areas of life – and where interests collide, there is the potential for conflict. From an evolutionary point of view, individuals' interests are almost exclusively related to reproduction. Thus, conflict between men and women is expected to arise when there is an asymmetry in reproductive interests and when the sexes pursue different mating strategies. These sex differences in reproductive strategies are largely explained by Trivers' (1972) parental investment theory, which states that there is a conflict for both males and females in how much time, effort, and resources to invest in mating versus parenting. The sex that makes the largest investment in offspring will also incur the highest costs from mating “mistakes” and as a result will be the most sexually discriminating, focus more on obtaining a long-term mate, and will be the sex in demand. In turn, the sex with the lower obligatory investment to compete more heavily with same-sex members for access to the higher investing sex and to adopt a more opportunistic, short-term mating strategy. In most mammals, including humans, one ejaculate during a sexual interaction suffices for males to pass on their genes to the next generation. For females, the minimally required investments are much larger. Should conception be successful, a female needs to invest in gestation and birth of her offspring, and after birth, lactation and childcare, causing females to be the more choosy sex. Thus, even though human males do invest heavily in offspring after birth (Geary 2000), women's obligatory or *minimum* parental investment is still larger than men's – causing intersexual conflicts. These conflicts – or rather, diverging reproductive interests – show themselves in mating strategies, mate preferences, and mate retention behaviors.

Mating Strategies

Among other things, discrepancies in minimum parental investments cause men and women to pursue qualitatively different *mating strategies* (Buss and Schmitt 1993), defined as the set of behaviors used by individuals to attract, select, and retain mates. If both sexes pursue their optimal mating strategy, conflict is likely to arise. Due to their higher physiological investments and the costs associated with these investments, women have evolved to be more discriminating about their sexual partners. Both a woman and her offspring would benefit most from a long-term, highly investing male, whereas men for men, short-term mating yields more reproductive benefits than long-term mating. Hypothetically speaking, a man mating with 100 women over the course of a year would likely have significantly more offspring than a woman mating with 100 men over the course of a year, which will likely only result in one pregnancy (Schmitt 2005). Indeed, compared to women, men report a greater desire for short-term relationships (Schmitt et al. 2001), have more permissive attitudes towards casual sex (Petersen and Hyde 2010), fantasize more about having sex with multiple partners (Malamuth 1996), and report desiring up to three times as many lifetime sexual partners (Buss and Schmitt 1993; Schmitt 2003). In a now-famous study, Clark and Hatfield (1989) showed that 75 % of the men but 0 % of the women approached by an attractive stranger of the opposite sex consented to a request to have sex that very evening.

However, just as long-term mating offers benefits to men, short-term mating may offer specific benefits to women. Greiling and Buss (2000) documented that women pursuing a short-term (extra-pair) relationship reported greater sexual benefits (e.g., having a partner willing to experiment sexually, obtaining greater arousal or being appreciated sexually), resource benefits (e.g., receiving expensive clothing or jewelry), and improvement of their attraction and seduction skills. Moreover, in addition to the differences between the sexes, there are also *within-sex* differences in the desire to engage in short-term

mating. Simpson and Gangestad (1991) introduced the Sociosexual Orientation Inventory to measure differences in people's willingness to engage in casual, uncommitted sexual relationships. Individuals can be classified on a continuum ranging from *restricted* – tending toward monogamy, prolonged courtship, and heavy emotional investment in long-term relationships, to *unrestricted* – tending toward promiscuity, quick to have sex, and desiring lower levels of romantic relationship closeness. Schmitt (2005) has shown that across 48 nations, consistent and large sex differences in sociosexuality appeared, with men generally being more unrestricted than women. Variation in sociosexual orientations, both between and within sexes, is likely to be partly influenced by environmental circumstances. For example, sex differences in sociosexual orientation are smaller in countries with more political and economic gender equality (Schmitt 2005).

As might be expected, the pursuit of qualitatively different mating strategies and the behaviors that follow from them might lead to considerable conflict between the sexes – after all, women might not be willing to consent to men's desires for casual sexual relationships, and men may not always give in to women's desire for commitment. Buss (1989b) focused on the specific emotions evoked by these kinds of conflict and showed that women were most likely to be upset and angered by men's greater sexual assertiveness and persistence. Men, on the other hand, were more likely to be angered and upset by women's tendency to require an emotional commitment before engaging in sexual behaviors. More recent studies have shown that men, particularly those who were focused on short-term mating and who rated themselves as attractive, tended to overperceive women's sexual interest (i.e., the overperception bias; Haselton and Buss 2000). Conversely, women tended to underestimate men's desire for a committed relationship (i.e., the commitment skepticism bias).

Conflicts over sexual access – men's greater desire and women's greater hesitation – can cause anger and frustration in men (Shackelford and Goetz 2004), which in turn increases the likelihood of sexual coercion. Sexual coercion can take

on more subtle forms – threatening to leave the relationship or withholding gifts if a partner does not consent to sexual intercourse – but may escalate to forcibly raping one's partner. As such, sexual coercion may be an extreme mate retention tactic, aimed at keeping the partner invested in the current relationship and keeping her (or him) from committing a sexual infidelity, and thereby reducing the risk of cuckoldry.

Mate Preferences

The type of mating strategy that is pursued also determines which characteristics are desired in a partner. Generally, the literature on mate preferences indicates that regardless of the type of relationship, both men and women value kindness, honesty, intelligence, and humor in a prospective partner (Buss 1989a), although there are also indications that these traits are considered luxuries rather than necessities (Li et al. 2002). Moreover, a long-term relationship requires both partners to make significant investments, which in turn causes both sexes to be more critical about a potential long-term partner's characteristics and to desire long-term partners with whom they can build a compatible and cooperative relationship (Li et al. 2002). Nonetheless, asymmetries in parental investments have caused sex differences in mate preferences, which are based on a prospective partner's reproductive potential – that is, the ability of an individual to invest in the growth, development, and competencies of offspring, and/or the genetic benefits he or she would confer to offspring. Thus, increased parental investment among men and women creates choosiness, which in turn causes the sexes to compete among each other in the domains the opposite sex values in a partner.

Women's Preferences

Given their larger obligatory investments in offspring and the associated higher costs of mating errors, it follows that women should be particularly choosy – for long-term mating as well as

short-term mating. Women's reproductive interests are served best from obtaining a long-term mate with the potential and willingness to invest social and material resources in her and their offspring (Buss 1989a). A man's reproductive potential is thus determined by his willingness to parent, his ability to invest material and social resources in his partner and children and genetic qualities which may increase his offspring's reproductive success. Because men with a higher societal status have better access to resources, women have evolved to value social status in long-term mates, as well as the internal attributes that signal the ability to attain high status or a leadership position – such as being a good judge of character, taking initiative, influencing people, and being assertive. Indeed, Li et al. (2002) showed that when mating decisions were highly constrained, women prioritized a minimum amount of social status before considering other mate characteristics. Thus, status seems a necessity rather than a luxury when women are choosing mates.

For short-term mates, women prioritize a male's physical attractiveness over his social standing (Li and Kenrick 2006), especially around the time of ovulation (for a recent meta-analysis, see Gildersleeve et al. 2014). Specifically, women require their short-term mates to be muscular, strong, fit, taller than they are, and masculine. Moreover, they tend to value bodily attractiveness over facial attractiveness for short-term mates (Li and Kenrick 2006). These preferences are in line with the strategic pluralism theory (Gangestad and Simpson 2000) which posits that given the trade-offs in mating and parenting, women are more likely to focus on desirable heritable qualities ("good genes") in situations where paternal investments are unlikely, such as in contexts of short-term or extra-pair mating.

Men's Preferences

For ancestral men, mating with a nonfertile woman would have been a reproductive dead-end. In women, ovulation is concealed, and female fertility peaks during their mid-20s and

declines afterwards. Men were thus faced with determining a woman's fertility based on external attributes and have evolved to focus on female physical qualities which signal fertility and youth due to their associations with high estrogen levels: full lips, soft hair, smooth skin, colorful cheeks, good muscle tone, and a low waist-to-hip ratio. Indeed, numerous studies have indicated that men place a premium on women's physical attractiveness, both for short-term and long-term relationships (e.g., Buss 1989a). However, similar to women, men prioritize bodily characteristics – particularly breasts and buttocks – over facial attractiveness in their short-term partners (Li and Kenrick 2006).

The search to attract the best possible mate causes sometimes fierce intrasexual competition, which is usually focused on the traits preferred by the opposite sex. That is, women compete within the domain of physical attractiveness, whereas men are more likely to compete over social status and resources. For most individuals, this competition causes a gap between what they ideally would prefer and what they can achieve. However, individuals with a high mate value are more likely to achieve their preferences and have greater reproductive success as a result. Indeed, high-income men report having more frequent sex and more biological children than men with a lower income (Hopcroft 2006), and highly attractive women are more likely to be married and have more biological children than less attractive women (Jokela 2009). In addition, men and women devote more effort to mate retention of high mate value partners than to lower mate value partners (e.g., Buss and Shackelford 1997).

Mate Retention

Once a partner has been successfully attracted, he or she needs to be retained. Some of the biggest conflicts between men and women can take place within a relationship, often causing the dissolution of the relationship. The loss of a partner inflicts costs on men and women, particularly a long-term

mate. One of the biggest threats to a relationship is a partner's infidelity, and worldwide, adultery is the leading cause of divorce and break-ups. To solve the adaptive problem of preventing a mate's infidelity, men and women have evolved sex-specific tactics to fend off intrasexual competitors and to retain their mate (e.g., Buss and Shackelford 1997). What the sexes have in common is a strong emotional response in the face of a threat to the relationship. *Jealousy* is evoked by the real or imagined presence of a romantic rival, and it involves feelings such as fear, suspicion, distrust, anxiety, and anger. Jealousy alerts the individual that the relationship is in threat, and it instigates a range of mate retention behaviors. Men and women differ in which aspects trigger their jealousy and the type of mate retention tactics they employ.

Jealousy Triggers

For men, a single sexual act of his partner with another male could result in a pregnancy, and thus, of him being cuckolded and unwittingly investing years of effort and resources in genetically unrelated offspring. Jealousy in men is thus hypothesized to be triggered more by his partner's sexual infidelity than by her emotional infidelity. In contrast, a woman's reproductive fitness is enhanced if she is able to monopolize her partner's investments and resources, and she must thus avoid her partner's redirecting these investments to another woman or child. Thus, a partner's emotional commitment to another woman – emotional infidelity – will evoke more jealousy in women than male sexual infidelity.

Indeed, when the two types of infidelity are pitted against each other and individuals are forced to choose the most upsetting element, more men than women select a partner's sexual infidelity as most jealousy-evoking, whereas more women than men report a partner's emotional infidelity as the most upsetting event (e.g., Buss et al. 1992). Similarly, men are more unforgiving of a sexual infidelity and more likely to break off the relationship because of it, whereas women found an emotional infidelity more unforgiving

and reason for a break-up. Since Buss et al. (1992) first reported these sex differences, this pattern of results has been replicated in numerous studies, across cultures and using different methods (for a meta-analysis, see Sagarin et al. 2012). Interestingly, these sex differences have been found to be enhanced in egalitarian societies (such as Norway) in which paternal investments are expected to be larger, and where the costs of a partner's infidelity are thus larger as well. Moreover, when there is *no* risk of conception – such as when an infidelity between an opposite-sex partner occurs with a same-sex rival – the sex differences in jealousy tend to disappear (e.g., Harris 2002).

Another sex-differentiated jealousy trigger is the rival itself. Specifically, the sexes differ with regard to the rival characteristics that are considered most threatening (for an overview, see Buunk et al. 2007). Specifically, since a woman's mate value is determined largely by her physical attractiveness, a romantic rival possessing such qualities will be attractive to men – and hence, threatening to other women. Indeed, studies have shown that women's jealousy is evoked most by physically attractive other women. Conversely, men's mate value is determined by his social status and economic potential, and it follows that for men, a rival displaying these qualities is most threatening. Indeed, these sex differences were repeatedly established, among heterosexual as well as homosexual individuals and across cultures.

Mate Retention Tactics

Once a threat to the relationship has been perceived, the necessity of mate guarding triggers behaviors aimed at retaining the partner. Men and women differ in the types of tactics they employ to retain their mate, as well as in the contexts in which these are employed. Among others, Buss and Shackelford (1997) showed that mate retention parallels mate preferences, such that men will attempt to retain their mate by engaging in resource displays like buying expensive gifts for their partner, whereas women are more likely to enhance their

appearance. Moreover, men more than women try to keep their partner away from other men and verbally and physically threaten their intrasexual rivals, whereas women are more likely to flirt with other men to evoke jealousy in their partners. More recently, research (e.g., Miner et al. 2009) has shown that a man's mate value is associated with specific types of mate retention tactics: Men with a high mate value are more likely to use mate retention behaviors that focus on enticing a woman to stay invested in the current relationship (e.g., by buying gifts), whereas low mate value men are more likely to engage in behaviors that function by inflicting or threatening to inflict costs on a woman for not remaining invested in the current relationship (e.g., by isolating her).

As the risk for infidelity increases, mate retention efforts are intensified. Having a mate with a high mate value increases the risk for infidelity and intensifies mate retention behaviors. Buss and Shackelford (1997) found that men married to attractive women and women married to high-income men reported more frequent and intense mate guarding. Also, men's mate retention efforts increase the more time they spend apart from their partners (Shackelford et al. 2007), and when their partner is near ovulation – a time when a female infidelity would be most costly (Gangestad et al. 2002).

Conclusion

Men and women differ in the obligatory parental investments necessary to ensure offspring survival (Trivers 1972), causing them to pursue qualitatively different reproductive interests. If both sexes pursue their own optimal reproductive mating strategy, conflict is thus likely to arise. This conflict is evident in (1) mating strategies – men desire and pursue short-term relationships, whereas women are focused on obtaining a long-term mate; (2) mate preferences – men place a premium on fertility and health, reflected in physical attractiveness,

whereas women desire a high-status, high-investing male; and (3) mate retention behaviors – men exhibit more mate retention behaviors when they are involved with an attractive female and when their partner is ovulating, whereas women perform more mate retention when their partner has a higher income.

Confluence Model

Mons Bendixen

Department of Psychology, NTNU – Norwegian University of Science and Technology, Trondheim, Norway

Definitions

The Confluence Model is a general framework for understanding developmental processes by tracing the mutual influences between the individual and his or her social environment as they unfold over time to shape some characteristic of personality (Kihlstrom 2018). The general framework of the model has been applied to the study of sexual coercion that involve sexual behaviors whereby one of the individuals does not fully consent to the acts. Sexual coercion covers the use of physical force, threat, deception, or intimidation (Huppin and Malamuth 2016). Examples cover forced kissing and touching, verbal derogation, sexual rumoring, showing sexually explicit pictures or objects, threats to end relationship, and insisting on having sex. Similar terms are sexual aggression, sexual violence, and sexual harassment.

Introduction

Throughout history, the typical perpetrator of sexual coercion is a male. Self-reports show that men are far more often perpetrators, and women targets of sexual coercion, and that this sex difference holds up across cultures (Huppin and Malamuth 2016). The Confluence Model of sexual coercion combines evolutionary and feminist approaches in an attempt to cover more ground than any competing single factor models that stems from either feminist or evolutionary theory. In its most basic form, the model incorporates two developmental paths, each with relatively independent sets of characteristics that may interact or *mutually* influence each other to increase the risk of sexual coercion (Malamuth 1986, 1996). Men who experience harsh early environment

characterized by parental violence and/or child abuse may be at risk of coercive behavior toward women through two different paths. The first path proposes that delinquency/antisocial behavior leads to attitudes condoning violence that again leads to hostile masculinity (i.e., Hostile Masculinity Path). This multifaceted construct stems from feminist theory and covers a variety of ways men may relate to women. Men who believe interpersonal relationships are fundamentally exploitative; who are defensive, insecure, and distrustful towards women; or who get gratification from controlling and dominating women are at greater risk of behaving in sexual aggressive ways. The second path, stemming from evolutionary theory, proposes that delinquency/antisocial behavior leads to sexual promiscuity, characterized by emotionally detached (i.e., *impersonal*) and short-term oriented sexual relations (i.e., Impersonal Sex Path).

Theoretical Approaches

Feminists claim that sexual coercion is motivated by men's desire to assert power over women (e.g., Sanday 1981). Using group conflict as a framework, proponents of the feminist perspective claim that men – to preserve male supremacy – have constructed a patriarchal social system to dominate women. Within this perspective, sexual coercion is just one of several strategies that men apply to dominate and control women. Rape is considered the ultimate form of domination and serves to preserve the status quo in the power distribution of the two sexes. In explaining mechanisms underlying men's rape and sexual assault on women, feminists claim men are socialized to become aggressive and dominant, while women are socialized to become tender and empathetic, submissive, and dependent. Central to the feminist approach is that boys and girls are subject to parental and societal treatment that breeds sex differentiated attitudes toward the use of violence and sex roles, as well as sex differentiated emotional expression, sexual behavior, and desire. Also, pornography exposure and consumption are assumed to adversely and directly influence

boys' attitudes toward women and sexual violence.

Evolutionary psychology claims that cooperation between men and women has typically increased the survival of their common offspring. Prolonged childhood required sustained coordination of resources in our ancestors, and selection pressures has designed adaptations for love and attachment, along with adaptation for collaboration and cooperation. Still, conflicts are prevalent, and in evolutionary terms these typically stems from differences in reproductive interest between individual men and women known as sexual conflicts (Buss 2017). Trivers (1972) has shown that minimal parental investment is markedly higher for women than for men (e.g., pregnancy, childbirth, and nursing). (Pregnant or breastfeeding women need on average an additional 500 kilocalories each day (adding up to an equivalent of 50 kg fat over a period of 2–3 years). In ancestral times, these could only have been provided by a highly investing partner with sufficient resources.) The potential costs for woman mating with a man who provided low or no investment would be high. Furthermore, the potential reproductive benefits for women mating numerous men would be low compared to men who mated numerous women. This asymmetry of costs and benefits has through selection designed the human mind with numerous sex-differentiated adaptations or mechanisms. Preference for short-term sexual relationships is one. In general, men and women differ considerably in their orientation to sex that is void of affection or emotional bonds. Relative to women, men are cross-culturally generally more open to casual sex, they are more ready to accept one-night stands, and they desire casual sex more (Schmitt 2005). Other mechanisms include sexual exploitation tactics and sexual misperception, both assumed to affect the likelihood of men sexually coercing women. Sexual exploitation is gaining sexual access by bypassing women's choice (e.g., approaching women who are intoxicated, sleeping, or vulnerable in other ways). Sexual misperception involves a systematic overperception of ambivalent cues to sexual interest. Within the sexual conflict approach, the conflicting reproductive strategies

and tactics of the other sex may cause anger and hostility in both sexes.

Empirical Status

The Confluence Model has been subject to modification over the years, and the most recent form – the Confluence Mediation Model – underlines the combined effects of distal factors, specific risk factors, and proximate situational influences on sexual coercive behavior, and where the effects of individual factors may be mediated and/or moderated by other factors in the model (Malamuth and Hald 2016). While the central concepts Hostile Masculinity and Impersonal Sex have been subject to somewhat diverse operationalizations, the model – repeatedly being subject to empirical testing – has with few exceptions proven robust in cross-sectional, longitudinal, and laboratory studies. Further, support for the two paths of the model is found across samples of incarcerated and noncriminal men (for a review, see Malamuth and Hald 2016). Distal factors such as prior sexual violence (or intentions to do so), being subject to child physical or sexual abuse, delinquency or conduct disorder, or exposure to parental violence or family conflict are all found to be associated with men's sexual coercion of women in most studies (Tharp et al. 2012). In most studies, the effects of these distal factors are fully accounted for by the effects of specific risk factors and situational influences (Malamuth and Hald 2016).

In support of the Hostile Masculinity Path, Murnen et al. (2002) reported in their meta-analytic review that sexual aggression toward women was moderately associated with measures of acceptance of interpersonal violence, beliefs in interpersonal relationships being fundamentally exploitative, dominance/power, hostility toward women, and rape myth acceptance. The latter has also been reported to be significantly associated with sexual violence in two more recent reviews (Tharp et al. 2012; Yapp and Quayle 2018). Several of the studies covered by these reviews had examined the effect of hostile masculinity measures within the frame of the Confluence Model.

In support of the Impersonal Sex Path, Tharp et al. (2012) and Malamuth and Hald (2016) summarized that early initiation of sex (age at sexual debut), higher number of sex partners, casual sex relationship status, and number of casual sex partners all increased the risk of sexual coercion of women in nearly every study examined. It is predominately the casual, uncommitted aspect of the sex – not general sexual drive, desire, or fantasies – that increase the risk of sexual coercion (Malamuth 1996). Tharp et al. (2012) also identified a number of specific risk factors associated with sexual coercion including sexual risk taking, misinterpretation of sexual signals, heavy alcohol consumption, and extensive exposure to pornography. The latter appears to influence sexual aggression propensity even when other factors are accounted for in the Confluence Model, but the effect of pornography also appear to be moderated by personality factors such as agreeableness (for details, see Malamuth and Hald 2016). In younger samples of adolescent students, pornography exposure is clearly associated with unrestricted sociosexuality and not with hostility toward women or rape myth acceptance (Kennair and Bendixen 2012).

One of the core predictions of the model is the *mutual* influence of Hostile Masculinity and Impersonal Sex variables in predicting sexual coercion of women. The effects of factors from each of these paths are assumed interact to produce particularly strong predictive effects. However, this contention has not consistently received empirical support. Across studies, the interactive (i.e., multiplicative) effect of factors does not always contribute to the prediction of sexual coercion over and above the additional effect (e.g., Abbey et al. 2011). Further, through its recent developments, the added complexity of model has made it less testable. Finally, the Confluence model considers impersonal sex an outcome of delinquency and harsh parenting. However, preference for uncommitted short-term sexual relations may be considered an aspect of personality that has shown similar level of heritability (Bailey et al. 2000).

Conclusion

The Confluence Model represents the most comprehensive model for testing factors associated

with men sexually coercing women today. The central premise of the model is the convergence of several factors organized into two major constellations, or paths, the hostile masculinity and the promiscuous impersonal sex paths. The model combines evolutionary and feminist approaches to the understanding of sexual coercion of women and has received good empirical support.

Confounding Use of Tools on Physical Tasks

Definition

Task manipulations that affect subjects' tool-use performance.

Introduction

Tool use is a widespread behavior among human and nonhuman animals (see Shumaker et al. 2011 for a review) and understanding which cognitive mechanisms underlie this remarkable behavior has been the subject of an important amount of research in the past decades (e.g., Sanz et al. 2013 for a review). Tool-use tasks that require subjects to overcome obstacles to get a reward have been important paradigms devoted to investigate causal knowledge in primates and birds (e.g., Call 2013). In this context, trap tasks – particularly, trap tube tasks – have been used extensively in recent years. Generally these tasks involve presenting subjects with a stick, a clear tube with a trap on its bottom part and a reward placed inside the tube next to the trap and outside of the subject's direct reach. Subjects have to use the stick to get the reward out of the tube while avoiding the trap in which the reward may fall (e.g., Visalberghi and Limongelli 1994).

Confounds in Trap Tasks

Strikingly, nonhuman primates perform quite poorly in trap tasks, and they require a large amount of trials to succeed. This poor performance has led some authors to argue that nonhuman primates fail to understand the causal relations between the different elements of this particular type of problem (i.e., tool, trap, and reward). Importantly, research has also shown that part of the difficulty of the trap-tube tasks is due to factors related to the specific presentation of the task. For example, the diameter of the tube and the tool might force the animals to push the reward out. This strategy might increase the difficulty of the problem, at least for nonhuman primates, since pushing the reward away increases

the distance between them and the food. In line with this observation, Mulcahy and Call (2006) presented great apes with a modified trap-tube task in which subjects could choose between raking the reward and pushing it out. Mulcahy and Call (2006) showed that subjects solved the task much faster than any other animals tested before. Another important finding was that in this modified trap-tube task great apes preferred to rake in rather than to push the reward out of the tube. Consequently, Mulcahy and Call (2006) suggested that forcing the subjects to get the reward by pushing it out might have caused the poor performance reported in previous trap-tube experiments.

While it is true that solving the trap task in few trials is consistent with the idea that subjects might have some level of causal understanding, it does not prove it. Other mechanisms – innate predispositions to avoid traps and learned heuristics (e.g., insert the tool in a particular location in relation to the trap position without understanding the effect that the trap has on the reward) – could produce equally successful behaviors. In this regard, previous studies have assessed the mechanism underlying performance in trap tasks by presenting subjects with the original trap task and a modified version of it. For example, Visalberghi and Limongelli (1994) used an inverted tube condition in which the trap was not functional because the tube was flipped 180°; therefore, the trap was above the tube and the bottom of the tube had no holes. The rationale behind this modification was that once the trap is nonfunctional, there was no need to avoid it. However, this modified version of the trap-tube task has been described as limited since there is no cost to continuing to avoid the trap. In order to circumvent this issue, Seed et al. (2006) developed a two-trap tube task in which a functional and a nonfunctional trap were located on the bottom of the tube. In two conditions, subjects – in this case, rooks – either had to push the reward into the nonfunctional trap to recover it from below or they had to avoid the functional trap and displace the reward over the nonfunctional trap in order to get the reward.

Although these conditions do control for some of the issues mentioned above, it is nevertheless vulnerable to criticism. This is because to succeed subjects could still be using learned heuristics rather than using the functional properties of the traps. Therefore, Seed et al. (2006) conducted two additional transfer tests, in which the causal relations integral to the task remained the same, but the appearance of the stimulus changed, thus preventing the use of certain perceptual features. Since one rook was able to transfer knowledge from the original trap problems to the two transfer problems, Seed et al. (2006) reasoned that the one subject might have understood something about the physical properties of the trap problem.

In a further attempt to investigate how successful performance is achieved in these tasks, Seed et al. (2009) presented great apes with two trap tasks: one that required the use of tools and one that did not. Strikingly, their findings showed that when eliminating the need for a tool, more subjects solved the task and they did so in fewer trials than subjects in previous trap task studies (e.g., Mulcahy and Call 2006; Povinelli 2000). The implications of this research are critical, and, as the authors argued, their findings suggest that “tool use is an activity that imposes cognitive demands of its own” (Seed et al. 2009, p. 33). In fact, Povinelli et al. (2010) have suggested that chimpanzees do not necessarily represent a tool as an extension of their body, and, therefore, tool use might require precise action monitoring. In this regard, trap tasks might be challenging problems because they involve not only having to avoid the trap but also monitoring the use of a tool. Therefore, when subjects only face one of these two problems (e.g., having to avoid a trap), their performance is remarkably improved.

More recently, Völter and Call (2014) presented great apes with a new trap task – a maze-like multilevel trap task. To succeed in this task, subjects were required to move a reward from the upper level of the maze to the bottom through open gaps placed at each of the three levels of the maze. Similar to Seed et al.’s (2009) study, Völter and Call (2014) investigated the role of tool use by presenting subjects with a condition

in which they could use a tool to move the reward and a condition in which no tool was needed – subjects could move the reward with their fingers. In addition, this new experimental paradigm allowed investigating the role that “planning” – defined as the anticipation of a series of sub-actions in order to achieve a final goal – played in trap tasks. Völter and Call (2014) argued that having to plan two actions (e.g., first, move the reward, and second, move the reward away from the trap) might have diminished subjects’ performance in previous tool-use trap tasks. Therefore, they expected that those subjects who had to use a tool to displace the reward would perform worse than those who did not – this would be particularly true when planning was required before making the first move. Völter and Call’s (2014) findings confirm previous studies showing that tool use imposes an extra cognitive load when subjects are asked to solve trap tasks (Seed et al. 2009). However, their results showed that tool use did not affect subjects’ planning abilities.

Theoretical Accounts

Thus far, research on tool-use trap tasks has shown that particular manipulations in the way the tasks are presented dramatically affect subjects’ performance. Strikingly removing a crucial component of these tasks – the tool – extraordinarily improves subjects’ performance. In an attempt to reconcile these findings, Frigaszy and Cummins-Sebree (2005) proposed a theoretical framework to help understand the mechanisms underlying performance in trap tasks. Their model incorporates the nature (i.e., egocentric or allocentric) and number of spatial relations, their temporal relation to each other (i.e., simultaneous or sequential), their specificity (i.e., prerequisite for a specific arrangement or orientation of one object to another or to a surface for efficient use), and their duration and stability over time (i.e., static or dynamic). What it is derived from this framework is that problems, such as trap tasks, are challenging because subjects have to consider two

concurrent issues – the use of the tool and the trap. Controlling the use of tool *and* understanding how the trap works might be a taxing cognitive activity when required to be performed in the same problem (Völter and Call 2014). Consequently, removing one of the actions from the problem (e.g., the use of the tool) facilitates subjects' performance (e.g., Seed et al. 2009; Völter and Call 2014).

Seed et al. (2009) have argued that at least three different factors could account for the cognitive load incurred by the use of a tool:

1. Splitting attention – the attentional load was suggested to depend not only on the complexity of the task but also on how familiar subjects are with particular action required in the task.
2. Cross modal matching – inferring functional information from visual appearance.
3. Response variability – individual preferences for certain actions (e.g., pushing away or raking in). While studies directly testing the role of tool use have offered empirical support for the first two factors (e.g., Povinelli et al. 2010; Seed et al. 2009; Völter and Call 2014), studies in which trap tasks presentation was manipulated provide some support to subjects' variability in tool-use preferences (e.g., Mulcahy and Call 2006).

Conclusion

Altogether understanding the cognition underlying animal tool use has been shown to be a complex enterprise. Contrary to what early studies on tool use, in general, and on trap tasks, in particular, had shown, some animal species can successfully solve these tasks when certain features are modified. Importantly, recent studies have also suggested that the use of tool imposes extra cognitive load, and, as such, it might hinder animals' successful performance. On this point, comparative studies on problem-solving abilities between tool-user and non-tool-user species will help to shed light on the role of tool use in cognitive evolution – since the few studies available on this issue are still far from being conclusive.

Congenital Adrenal Hyperplasia (CAH)

Craig Bielert

The State University of New York, Oneonta,
NY, USA

Synonyms

[Adrenogenital syndrome](#); [Hyperadrenocorticism](#)

Definition

A genetic disorder present at birth characterized by a deficiency of the hormones aldosterone and cortisol and an overproduction of male sex hormones (androgens). In males this may manifest as enlarged penis, small testes, and early development of masculine characteristics. In females features include ambiguous genitalia, failure to menstruate, deep voice, and excessive hair.

Introduction

In 1932, the book *Sex and Internal Secretions* was published under the editorship of Edgar Allen. It represented a state-of-the-art compendium of work in the area of reproductive physiology and endocrinology. It went through three editions; the third and final was published in 1961, with W. C. Young as editor.

A quick check of the subject index fails to find a listing for “congenital adrenal hyperplasia.” There is, however, a listing for “hyperadrenocorticism,” and reference is made to pages found in chapters authored by J. Money and J. H. Hampson and J. G. Hampson. Today, if one googles “adrenogenital syndrome” or “salt-losing adrenogenital syndrome,” one will come up with 205,000 and 5,100 references, respectively.

Congenital adrenal hyperplasia (CAH) is the most prevalent cause of intersex for individuals with an XX karyotype. Its frequency of occurrence is reported as 1 in 10,000–18,000

(www.isna.org/faq/conditions/cah). The most common cause is a 21-hydroxylase deficiency. Affected individuals are exposed in utero to super-normal androgen levels as a result of excessive production of sex steroids, predominantly C19 steroids. In the case of genetic (XX) females, this androgen exposure may result in masculinization of the developing external genitalia, and such individuals were once referred to as “pseudohermaphrodites.”

The level of masculinization shows considerable variation. The neonates’ genitals can be rated on a five-stage progressive scale, developed by Andrea Prader and referred to as the “Prader scale.” The level of masculinization depends upon the timing of the exposure and the level of circulating androgens. The external genitalia develop during week 8–13 of gestation. This is often referred to as an embryologic “critical period.” If androgen levels are high between weeks 8 and 12, there will be labial fusion and the formation of a urogenital sinus. The genital tubercle, in rare cases, goes on to develop into a functional penis. If the exposure occurs after week 12 when the vagina and urethra have separated, only clitoral hypertrophy occurs. Genetic males (XY) with CAH don’t exhibit any hypertrophy of their external genitalia, as the fetal testis typically produces adequate testosterone, which is converted by 5- α reductase to dihydrotestosterone for genital development.

At early stages of embryologic development, embryos have both Wolffian and Mullerian duct systems. In genetic males, the fetal testes produce testosterone as well as Mullerian inhibitory factor (MIF); as a result, the Wolffian system proliferates and the Mullerian ducts regress. Genetic females don’t produce either testosterone or MIF, and the default developmental pathway for the human is that of Mullerian system proliferation, so the fallopian tubes, uterus, and upper vagina develop normally. In genetic females with CAH, the levels of adrenal androgen don’t appear sufficient to support Wolffian duct development, since, even in the most extreme cases, there is no obvious Wolffian development.

There are three different steroidogenesis enzyme deficiencies which may lead to

masculinization: (1) 3 beta-hydroxysteroid dehydrogenase deficiency (classic and nonclassic CAH), (2) 21-hydroxylase deficiency (salt-wasting, simple virilizing, and nonclassic CAH), and (3) 11-beta-hydroxylase (hypertensive classic and nonclassic CAH). All types of CAH require appropriate case management.

Early Work

According to Feder (2014), “examination of the history of CAH is a complicated matter. Though today it is clear that there is a close identification of genuine medical problems caused by CAH with the social problem atypical sex is taken to present, this was not always the case. Indeed, there is little evidence that ‘hermaphroditism’ . . . was associated with any condition we would regard as a disease or malady, as most forms of CAH obviously are now recognized to be” (Feder 2014, p. 25).

In the 1950s, Lawson Wilkens established a fellowship in pediatric endocrinology at Johns Hopkins Hospital. It was at this same time that John Money began his career at Johns Hopkins. Money joined John Hampson and his wife Joan; both of the Hampsons were psychiatrists and this couple, along with Money, was staff in Hopkins’ Psychohormonal Research Unit. It was this unit that developed an intersex care management routine, the “Hopkins Protocols,” as the five publications by this group, appearing between 1955 and 1956 in the *Bulletin of the Johns Hopkins Hospital*, came to be called.

In 1964, William Young, Robert Goy, and Charles Phoenix published a paper in *Science* in which they suggested that gonadal hormones had two specific forms of action in mammals. Fetal testosterone has an “organizational” action on developing organs, including the brain. The outcome of this action is anatomic and behavioral masculinization. The second gonadal hormone action is “activational” and begins at puberty. The hormones at this time bring about the development of secondary sexual characteristics and stimulation of species-specific sexual behavior. Work by Harry Harlow in 1965 established

that surrogate-reared and peer-socialized rhesus monkeys (*Macaca mulatta*) exhibit a number of sexually dimorphic behavior patterns during their prepubertal period. Goy provided validation of the “organizational hypothesis” by documenting the masculinization of the behavior of genetic female rhesus exposed in utero to testosterone propionate. More importantly, follow-up work by G. Eaton, R. Goy, and C.H. Phoenix with these pseudohermaphrodites as adults documented their ability to perform ejaculatory behavior with female partners when under testosterone treatment.

John Money, in his previously mentioned chapter, “Sex Hormones and Other Variables in Human Eroticism,” from *Sex and Internal Secretions*, reported on the situation of a total of 21 female hyperadrenocortical hermaphrodites who had been precociously virilized and then studied when feminized on cortisone therapy. Money stated that “only one of the older patients elected against, and none regretted a decision in favor of this feminizing procedure” (the surgical procedure referred to includes the reduction of clitoral hypertrophy) (Money 1961, p. 1398).

In their chapter, “The Ontogenesis of Sexual Behavior in Man” in Young’s book, the Hampsons cite work with 44 cases of hyperadrenocortical syndrome patients. In their final summation, they state, “one can conclude that an individual’s gender role and orientation as boy or girl, man or woman does not have an innate, preferred instinctive basis as some have maintained. Instead the evidence supports the view that psychological sex is undifferentiated at birth, a sexual neutrality in place of a Freudian bisexuality, and that the individual becomes differentiated as masculine or feminine, psychologically, in the course of the many experiences of growing up” (Hampson and Hampson 1961, p. 1413).

In 1972, John Money and Anke Ehrhardt published the book *Man & Woman, Boy & Girl* and in it presented data that he had collected on a group of 15 adrenogenital patients and their matched controls. In the chapter “Fetal Hormones and the Brain: Human Clinical Syndromes,” Money discusses not only sexual play but also

other behavior categories that appeared to be sex or gender dimorphic. These categories are: (1) Evidence of Tomboyism, (2) Expenditure of Energy in Recreation and Aggression, (3) Preferred Clothing and Adornment, (4) Maternalism, (5) Marriage, and (6) Romance. In the case of the presented data, there were significant differences of at least $P < 0.05$ on 9 of the 15 specific queries put to his subjects. However, Money doesn't discuss whether this seems consistent with the idea of androgen-related masculinization. Money discusses how cortisone treatment of this disorder began in the 1950s and thus prevented affected individuals from continuing postnatal androgen exposure. Money comments upon the situation of his androgenital cases in the following fashion:

There were some late-treated women with the adrenogenital syndrome who, even prior to cortisone treatment, manifested relatively little behavior that might be classified as more typically masculine than feminine. These women show that postnatally elevated androgen levels, persisting into adulthood, do not in and of themselves dictate a masculine gender role or gender identity. They also show that, if there is a permanent prenatal hormonal effect on a part of the central nervous system that mediates sexually dimorphic behavior, then it obviously is in some way selective. The selectivity may pertain to the timing and/or amount of fetal androgen exposure. An alternative explanation may be that postnatal gender-identity differentiation may be capable of overriding prenatal precursors, or at least of modifying them to an extensive degree. (Money and Ehrhardt 1972, pp. 104–105)

Money was a proponent of “sex neutrality” at birth, and The Johns Hopkins clinic treated intersex patients in a fashion consistent with this position. Money buoyed up this interpretation by referring to the success which had been achieved in the treatment of a genetic male who had suffered the loss of his penis during a botched circumcision. As John Colapinto (2000) points out, references to this case, which was under Money's management, are scattered across the introduction. Money suggested that any negative sequelae from his patient's gender reassignment were lacking. This would have been a medical success story if it had been accurate; however, Money was not truthfully presenting his patient's progress. In

reality, his patient experienced depression and instability and never felt himself to be female. There was eventually a second reconstructive surgery to re-masculinize his genitals as well as a name change from Brenda to David.

Paradigm Shift

The work carried out at John Hopkins is certainly important to a consideration of the organizational effects of gonadal hormones. In the case of humans, experimental work is ethically impossible, and so clinical cases, experiments of nature, become the appropriate approach. In the case of nonhumans, the identification of sexually dimorphic behaviors is fairly routine, and those that don't require concurrent hormonal support become most appropriate for a consideration of the validity of the organization hypothesis (e.g., canid urination patterns, prepubertal primate play, and sex behavior). The identification of appropriate sexually dimorphic behavior patterns for humans is more problematic. There are, however, a number of traits which seem to be commonly accepted, and these include (1) sexual behavior, (2) sex-typical, (3) spatial ability, (4) language facility, (5) aggression, (6) exploratory behavior, and (7) playmate preferences.

CAH is a clinical condition in which genetic females may end up virilized as a result of in utero exposure to abnormally high levels of adrenal androgens. Depending upon the timing and level of hormone response, the affected individuals should show behavior frequencies which are shifted in the direction of normal genetic males. In Money's first presentation of CAH psychosocial behavioral profiles, he included data on progestin-induced pseudohermaphrodites because he felt that the in utero androgen exposure the patients had received made them an appropriate comparison group for his CAH subjects. Perhaps an even more appropriate control subject group might be genetic female twins who were in utero with an opposite-sexed partner. There are studies that have examined possible sequelae from such exposure on a number of sexually dimorphic patterns, such as tooth eruption, attitudes, eating

disorders, and mental rotation performance. The paper by Vuoksima closes with the following assertion: “Finally, our results may reflect both prenatal hormonal and postnatal environmental factors, and these factors may be inextricably linked: Prenatal exposure to testosterone may subtly masculinize females, with the result that these girls may gravitate toward male-typical activities that enhance mental rotation ability” (Vuoksima et al. 2010, p. 1071).

Because of the in utero exposure to adrenal androgens, genetic female girls presenting with CAH should exhibit behavioral masculinization on those behavior patterns which have been identified as sexually dimorphic. In the case of humans, such validation of the organizational effects of prenatal androgen exposure has been reported for (1) aggression and activity and (2) toys and activities. Interestingly, work with vervet monkeys (*Cercopithecus aethiops*), as well as rhesus monkeys (*Macaca mulatta*), has provided data suggesting that a biological substrate may underlie the dimorphisms present in the play behavior and exploration shown in the nonhuman species. The biological basis for sexually dimorphic behaviors is certainly well-documented in nonhuman mammalian species. Studies of primates by Goy and others such as Melissa Hines and Kim Wallen have extended to a variety of topics. There are also data available relevant to the organizational hypothesis in the case of primates from a chacma baboon (*Papio ursinus*), caught in the wild as an adult, that presented as an XY male with gonadal dysgenesis (Bielert et al. 1980). This animal was deprived during development of the fetal testes outputs of testosterone and Mullerian inhibitory factor and as a consequence had a preadolescent female phenotype. When tested with appropriate sexual partners, it was clear that female behavior was exhibited at normal levels and that testosterone treatment was responded to in a fashion consistent with that of a genetic female (Bielert 1984). For human males presenting with complete androgen insensitivity, a female gender identity is adopted, and a female-typical sexual orientation (they are sexually attracted to men) was self-reported

(Wisniewski et al. 2000). Not unexpectedly, a report on the sex behavior of CAH females documented that most of the subjects were heterosexual but that the rates of bisexual and homosexual orientation were increased above controls (Meyer-Bahlburg et al. 2008).

Future Efforts

In the case of humans, it is relevant to consider cross-cultural differences in the view on and management of intersex conditions (Warne and Raza 2008). A study of young patients with CAH done in Malaysia confirmed reported increases in aggression for their CAH subjects, pointing out, however, that mean “T” scores of the children with CAH fell within the normal ranges of the normative sample, and closed with the suggestion that future studies be encouraged to insure a sample size sufficient to produce a rigorous study methodology (Idris et al. 2014). Studies on CAH have continued to receive detailed discussion in sources such as Cordelia Fine’s book *Delusions of Gender* and Robert Sapolsky’s recent volume, *Behave*. The suggestion made in Fine’s most recent book, *Testosterone Rex*, that studies focus on what particular features of boyish toys appeal to the male brain and what toy features might lead to nurturant activity, seems totally appropriate. Studies of this sort can build on work such as that by Corrine Hutt.

Conclusion

Future work in this area should be encouraged. It is time to approach sex and gender behavior differences in a more cautious fashion. Clinical studies on disorders of sexual development will continue to be important sources of information relevant to an appropriate consideration of the effects of in utero hormonal exposure as related to sexually dimorphic behaviors, and attention to their effective management should remain a concern (McCarthy et al. 2017).

Awareness

Definition

An individual's awareness about self and its external environment

Introduction

The Cambridge English Dictionary describes consciousness as “*the state of understanding and realizing something*” (Dictionary 2017). A conscious state is characterized by access to a wide range of information to the brain at a point of time (Dehaene and Naccache 2001). Consciousness is a broad phenomenon. Attempts have been made to define various forms of consciousness. Self-consciousness is a form of consciousness where the awareness is focused on self (De Graaf et al. 2012). The individual who is aware of his or her physical, psychological, financial, social as well as spiritual state can be said to be fully self-conscious. An individual's self-consciousness varies from time to time. At a particular point of time, self-consciousness about physical well-being (e.g., health, body image) may be more evident, whereas at another point of time some other self-construct may be overemphasized. A form of higher-order consciousness makes humans aware of their past, present, and future (De Graaf et al. 2012). It helps in understanding the present and correlating or attributing it to the past and the future. It

also helps in making assumptions and predictions.

Consciousness: Perspective from Neuroscience

Consciousness is a fundamental brain activity. Consciousness is highly desired for performance of any cognitive task. Conscious activities need intactness of attention. Information processing and task performances operate at the conscious level as well as the subconscious level. Tasks operated consciously involve neuronal circuits that work coherently under top-down magnification of attention (Dehaene and Naccache 2001). The human brain contains various specialized neuronal networks for processing of information. Many of these networks process information that is readily available, whereas several other networks work in parallel to process information that is not readily available to conscious awareness, hence, referred to as unconscious processing of information (Wallace 2005).

Consciousness is predominantly (though not purely) an activity of the cerebral cortex. Cerebellum, though contains more neurons is not involved in regulation of consciousness (Tononi and Koch 2015). The prefrontal cortex, anterior cingulate cortex and their associated brain areas (reticular activating system) are responsible for maintaining consciousness (Dehaene and Naccache 2001). The working memory functions in close association with consciousness. The conscious state of mind readily accesses information from surroundings as well as from the memory stores (past experiences), which is required for task performance (Soto and Silvanto 2014).

Consciousness is a state. In a healthy individual, it fluctuates between fully awake state and deep sleep. In illnesses, it may get further diminished to the level of coma. Hence, it can be said that consciousness states range from comatose condition to fully awake state. These states are referred to as “state consciousness” (De Graaf et al. 2012).

A conscious state of mind carries many contents. These contents are mostly experiential (past

experiences stored in memory store) or factual. It refers to “content consciousness.”

Minimal consciousness is a state that refers to “individuals who show minimal evidences of consciousness and are unable to communicate” (Laureys et al. 2014). It is often seen in states resulting from extensive brain damage and during this state pain perception and emotional processing activities remain intact.

Consciousness is not merely being aware and responding to stimuli. An individual who is awake is not always conscious. Evidences support, that people with severe brain damage may have a state, where eye movements and opening are normal, as if the individual is awake but does not show any response to stimuli. A conscious individual is capable of experiencing stimuli, making prediction of events (anticipating), and will be capable of making decisions (Tononi and Koch 2015).

Consciousness: Psychological Perspective

In the brain, mental activities (e.g., information processing) occur continuously. Most of the mental activities are happening without the awareness of the individual, hence considered as unconscious in nature. Similarly, the brain receives information from multiple sources and attributes meaning to them, which do occur in a similar fashion (i.e., unconsciously) (Solms 1997). Conscious awareness results from the interaction between external perceptions (environmental stimuli), internal perceptions (experiencing emotion), and cognition (memory of life experiences) (Solms 1997).

Sigmund Freud had attempted to explain consciousness in his topographic theory of mind (Macmillan 2009). As per this theory, mind can have three processes: conscious, preconscious, and unconscious. Conscious process refers to the active awareness of mental activities and preconscious process refers to those ideas or mental activities that need effort to reach conscious awareness. Unconscious process is out of reach from the active awareness. The primary process “Repression” operates to conceal the unwanted or unacceptable ideas or thoughts (Macmillan 2009).

Unwanted interference of ideas or thoughts from preconscious state may affect the conscious state of mind, which is prevented by a mental force acting on the conscious–preconscious interface (Macmillan 2009).

Consciousness: From the Perspective of Spirituality

Explanatory models from spirituality explain consciousness as a journey that aims at expanding awareness from meeting the needs of sustainability to a state of flourishing (Heaton 2016). From a spiritual and philosophical perspective, consciousness has been one of the most difficult topics to address. Therefore, it has been aptly named by some as the “hard problem” (Shear 1999). The concept is too broad to be discussed in this brief chapter and hence, would be only superficially touched here. The Western philosophers describe consciousness in terms of either “dualism” or “materialism.” According to the theory of dualism, conscious mind is nonphysical in nature. Some may equate this “nonphysical” nature with that of spirit or soul, as described in various religious texts but the two views may not be necessarily similar. Further, this approach says that consciousness is nonphysical in nature and thus, not only is it invisible but is also beyond the reach of any physical instrument. Also, it is believed that the nonphysical consciousness and the physical/material body interact with each other in a complex manner and affect each other (Havlik et al. 2017; Sharma 2018; Gennaro 2019).

On the other hand, materialism believes consciousness is a by-product of neural activity of brain. This theory is easier to believe in light of the explosion of scientific knowledge and the invention of sharper scientific instruments that can record the most subtle activities of the brain. However, despite so many advances, there are significant explanatory gaps and materialistic theories are not able to explain all, thus leaving sufficient scope for other theories (Havlik et al. 2017; Gennaro 2019).

The Eastern philosophers have an entirely different view of consciousness. Here, it is believed

that consciousness is a matter of a different kind, i.e., *Prana*, or manifestation of cosmic energy. The Divine is the ultimate source of all cosmic energy and one could experience this divine energy within oneself through enlightenment. The state of enlightenment could be experienced through meditation and achieving a state of super-consciousness (Heaton 2016; Swift 2019). The Vedic philosophy, which has given birth to *transcendental meditation*, emphasizes on serial expansion of the horizon of consciousness through the meditative process in order to maintain harmony between mind-body-soul (Heaton 2016). The Vedas and the Upanishads clearly depict various levels of consciousness (lower consciousness: “ordinary state of wakefulness”; higher consciousness: “extra-ordinary state of awareness”). This extra-ordinary state is a state of harmony between existence, knowledge, and positive emotions (*sat-chit-aananda*) (Rao and Paranjpe 2016).

The Buddhist philosophy emphasizes on the state of consciousness (awareness). The mindfulness meditation, based on the Buddhist philosophy, encourages one to be conscious about the thoughts, emotions and behavior for their effective regulation (Rao and Paranjpe 2016).

Measuring Consciousness

The Glasgow Coma Scale (GCS) was developed to measure the level of consciousness, and over the past four decades, it has proved to be a useful tool for bedside assessment of depth of consciousness (Teasdale and Jennett 1974; Teasdale et al. 2014). It measures three different domains: best motor response, verbal response, and eye opening. It is simple and can give an accurate account of the depth of consciousness; hence, doctors as well as paramedics can use it without much assistance (Teasdale et al. 2014). The limitations of the GCS are: non-consideration of corneal reflexes, pupillary reaction, seizure or myoclonus into account. Similarly, in intubated patients, the verbal response score goes low, as a result of which the overall level of consciousness might be wrongly interpreted (Laureys et al. 2014).

Emergency Coma Scale (ECS) can be an alternative to GCS, for measuring the depth of consciousness (Takahashi et al. 2011). ECS quantifies the level of consciousness by taking eye opening, verbal response, motor response and orientation into account (Takahashi et al. 2011).

Consciousness: The Dilemma

In spite of the advancement in science, understanding the exact neural correlates of consciousness remains elusive. If consciousness is a matter of neuronal density and integrity, then cerebellum contains more neurons with integrity. If consciousness is all about awareness, responding, and predicting, then in this modern era, advanced computers and robots can do it faster and more accurately (Tononi and Koch 2015). But, is that all that accounts to consciousness? If yes, then something is missing unfortunately. If the answer is no, then extensive research is needed to understand the complex phenomenon of consciousness.

Conclusion

Consciousness is a basic function of the brain and is a complex phenomenon. With the help of consciousness, an individual meets the bare needs of life as well as the higher goals of life (spiritual enlightenment). Consciousness is a complex process in the brain that makes an individual aware of his/her body, mind, and soul so that the individual will be able to meet his/her survival needs as well as satisfying (pleasure) needs.

Definition

Consequentialism is a metaethical theory which requires that all the consequences of an action figure in determining whether it is right or wrong. The minimization of suffering and maximization of pleasure are the general desiderata for consequentialist moral evaluation.

Introduction

Suffering characterizes the human condition. This is evinced by the pivotal position it maintains in both the Christian doctrine of atonement and Buddhism's central focus on overcoming the suffering of oneself and others. From a general secular perspective, we recognize the breadth of possibility, the myriad courses of action open to us given our natural abilities, and despair in the knowledge that we can but satisfy relatively few of our desires. Nothing pains us more than our brute limitations, the stark fact of personal and collective potential unrealized. It is in the shadow of

Historically in the Western world, adherence to theism has provided a salve to this predicament. It is at least plausible that an omnipotent, omniscient, and benevolent deity (not unlike the God traditionally conceived of in Abrahamic religions) chose to create, as G.W. Leibniz suggests, "the most perfect world, that is, the one which is at the same time the simplest in hypotheses and the richest in phenomena" (Leibniz 1686, pp. 39). The perfection attributed to any such deity, following Isaac Newton's great discoveries in mechanics, was seen as inversely proportional to the need for miraculous intervention in the natural order. For a truly omniscient and omnipotent god would foresee the need to intervene and simply realize a different state of affairs if such a state was in any sense better for those supposedly created in the divine image. A deity that acts at a remove via natural laws or processes, or what are sometimes called "secondary causes," was considered more perfect than a god who must constantly intervene so as to correct or even alter aspects of its own creation. The lesson regarding the occurrence of human pain and suffering in this ideological framework was stark: Thank God it isn't worse!

Theological optimism of the foregoing variety, while not explicitly inconsistent, has nevertheless been strained to the breaking point in light of Charles Darwin's theory of evolution by way of natural selection. Darwin, a committed albeit liberal Christian throughout his early adulthood, labored mightily under the intellectual burden that accompanies accepting natural selection as the mechanism by which evolution proceeds. Nowhere is this struggle more forthrightly conveyed than in a 1960 letter he penned to one of his American contemporaries, the Harvard University botanist Asa Gray:

I own that I cannot see as plainly as others do, and as I should wish to do, evidence of design and beneficence on all sides of us. There seems to me too much misery in the world. I cannot persuade

myself that a beneficent and omnipotent God would have designedly created the Ichneumonidae with the express intention of their feeding within the living bodies of Caterpillars, or that a cat should play with mice. (Darwin 1888, pp. 105)

For Gray and Darwin alike, the problem was one of how to reconcile the idea of a beneficent deity with observations of atrocities transpiring in the biological realm. Nor was this exclusively a preoccupation of the nineteenth century mindset. With regard to the evolutionary process, philosopher Phillip Kitcher has recently remarked that, “Indeed, if we imagine a human observer presiding over a miniaturized version of the whole show, peering down on his “creation,” it is extremely hard to equip the face with a kindly expression” (Kitcher 2007, pp.124).

By far the most common way of responding to this “problem of natural evil” was (and for some still is) to depict the evolutionary process as ultimately progressive in spite of appearances to the contrary. This riposte predates Darwin’s elucidation of the mechanism behind evolution. Alfred Tennyson’s wildly popular poem *In Memoriam A. H.H.* (1850), a meditation on mankind’s place in the natural order and impact of scientific ideas like evolutionism on religious faith, is perhaps the quintessential example in this regard. In it he muses,

*Are God and Nature then at strife,
That Nature lends such evil dreams?
So careful of the type she seems,
So careless of the single life;
That I, considering everywhere
Her secret meaning in her deeds,
And finding that of fifty seeds
She often brings but one to bear,* (Canto LV, stanza 2–3)

The “single life” is presented to his Victorian readership as nothing but fodder for the evolutionary process. There is precious little grandeur in this view of life. If, however, such sacrifices are ultimately for the greater good, the consequences to which our all too human limitations blind us, hope remains:

*Who trusted God was love indeed
And love Creation’s final law –
Tho’ Nature, red in tooth and claw*

With ravine, shriek’d against his creed – (Canto LVI, stanza 4)

There is indeed a cosmic purpose or grand design if only we could but comprehend it. For the more sophisticated adherents of theistic evolution, then, the diversity of form and function in the living world can in fact be the result of evolution via natural selection conceived of as a secondary cause. Against those who would counter that careful scrutiny reveals natural selection to be a wasteful and cruel process, the theistic evolutionist appeals to human ignorance and limitation. We must judge the outcome and process from a blinkered perspective, one from which our world looks less like the product of perfection than it does the tinkering of a powerful but morally ambiguous entity. But if properly understood as a progressive goal-directed process, the ultimate purpose of which is to set the stage for human life and flourishing, evolution by means of natural selection is purportedly worth the titanic cost.

The Ends of Suffering Reconsidered

While such unfettered theological optimism may provide comfort to some, others find it badly wanting. Notice that it offers an unabashedly consequentialist justification. Consequentialism, a metaethical theory, requires only that all the consequences of an action figure in determining whether it is right or wrong. This leaves considerable room for differences of opinion over what makes for a *morally relevant* consequence. Pairing this permissiveness with a commitment to the idea that ends can justify means permits the theist’s construal of evolution as a genuinely progressive process (Ruse 1996). Suffering, especially of the nonhuman (animal or even early hominin) variety, is allegedly acceptable because it is presumed to be the means to a worthwhile outcome, namely human flourishing. For this conclusion to follow, human suffering would have to be of a fundamentally different qualitative kind or at least substantially different in terms of quantitative degree. Since Aristotle’s *De Anima* thinkers

the world over have urged it as a difference in qualitative kind. But establishing a mere difference in kind does not suffice to license unequal ethical consideration. It must also be shown that human suffering (and its complement pleasure) is of a kind which holds greater moral significance. That this is the crucial presupposition becomes all the more evident when noting that more than 99 % of all species that ever lived on Earth, roughly five billion species, are extinct (Stearns and Stearns 2000, pp.1921).

Justification for the inequality between human and nonhuman suffering is usually drawn from the work of philosopher John Stuart Mill. For Mill, the “higher” pleasures, such as those experienced when reading poetry or listening to Beethoven’s ninth symphony, are fundamentally different in kind from the “lower” human pleasures out of which they arise. Higher pleasures are more satisfying and, thereby, lend to greater overall happiness, which is the ultimate moral desideratum for a utilitarian consequentialist like Mill. While nonhuman animals might very well be sentient in the minimal sense that they have an interest in avoiding pain and suffering, the avoidance behavior that they exhibit is only instrumentally good as a means to satisfying the immediate base desires associated with survival and proliferation. Animals are not, according to this view, equipped for experiences like existential dread, anguish over the future prospects of their offspring, or lamenting the plight of genetically unrelated individuals at a geographical remove. Just as higher human pleasures are preferable to base human pleasures, so, too, is human pain and suffering supposedly superior to nonhuman suffering. Human sentiment was consequently thought to deserve more consideration in moral calculations. It was in this sense that Mill could claim that it is better to be Socrates dissatisfied than a pig satisfied (Mill 1861).

Roughly parallel thinking pervades the rationalizations of those who would accept the evolutionary sacrifice of countless nonhuman lives for human flourishing. But the problems facing this line of argument are daunting. First, it is less than obvious that the suffering

experienced by animals with sophisticated nervous systems merits any less moral consideration simply because it happens to be of a “lower” or instinctive variety. Animal rights and welfare advocates have offered cogent arguments to the contrary (Singer 1975). Second, even if one grants that the suffering of any token nonhuman is of a “lower” type and thereby of lesser moral worth relative to that experienced by a human, the sheer amount of animal suffering taken collectively over evolutionary time might well be enough to offset the happiness enjoyed by all current and future humans. A third problem is one of omission. While many find the trade of nonhuman suffering for human flourishing acceptable, intuitions diverge when the tradeoff involves the suffering of people in the past for the well-being of current or future humans. Human suffering has occurred on an epic scale. Only some of that human suffering can be attributed to evil or ignorant human acts. A good deal of human suffering has thus been due to natural causes. Theistic evolutionists must conclude that such past human miseries are collectively of lesser moral worth in the final reckoning: there is, or at least will be, greater human flourishing as a result. But this hedonic calculus involves more mystery than mathematics. For if nothing else, the legions of the tragically deceased continue to swell and will vastly outnumber the extant population at any foreseeable time. Perhaps just as worrisome is that our current (nature-induced) pain must also be worthwhile insofar as this suffering purportedly enables the well-being of future generations. At minimum, one can certainly understand why many remain unconvinced by the theological case for moral progress via suffering.

For others, it is nothing short of ironic that theistic evolutionists should resort to consequentialism as a way of addressing the issue of suffering. To see why, one must first understand how the maturation of population genetics and especially the advent of molecular genetics transformed questions about human suffering. If natural selection drives evolution via the differential survival and reproduction of heritable variations, favorable variations cannot be redistributed

randomly in subsequent generations. There must be some sort of transmission fidelity or inheritability between the fitness-enhancing phenotypic traits found in parental generations and the prevalence of such traits in offspring for cumulative adaptive evolution to occur. Discoveries involving the biochemical structure of genotypes revealed how and why transmission across generations is a more or less reliable and predictable process. But in so doing, it also engendered a new set of questions regarding the entities that are subject to the process of natural selection and the beneficiaries of selection, not to mention what it is that is being reliably transmitted from one generation to the next. Addressing these questions typically requires a distinction between “replicators” – entities which pass on their structure more or less intact through successive replications – and “interactors” – entities which bear traits and interact with their environment via those traits in such a way that their expected survival and reproductive success is determined partly by this interaction (Hull 1988). For most, molecular genes were obvious candidates for the role of replicators, while the individuals that bear phenotypic traits are better cast as interactors.

The implications of this division for the issue of human suffering could not be more profound. Within a theistic worldview, the “problem of moral evil” could be evaded by citing the existence and desirability of human free will. Morally evil acts and consequent suffering were cast as the outcome of error-prone humans acting in ignorance or with weakened resolve. This state of affairs was nevertheless preferable to a world in which initial conditions and natural laws determined all subsequent action on the grounds that cherished notions relating to moral responsibility are rendered seemingly irrelevant by hard determinism. But natural selection cares only for consequences measured in terms of the relative number and viability of the copies of genes (or gene combinations) produced in subsequent generations. The thoughts and intentional actions of human agents, when seen as evolutionary interactors, are of importance only insofar as these happen to coincide with the

survival and reproduction of the genes that they house.

Conclusion

At one fell swoop suffering’s role as one of the most intimate and powerful psychological motives in human history is reduced to its efficacy in directing the fleshy vehicles driven by our genes away from evolutionarily precarious situations. It is this “pitiless indifference” (Dawkins 1995) toward individual suffering and the apparent mockery it makes of free will that continues to disillusion human sensibilities. Theistic evolutionists were not so much wrong in thinking that consequences matter; it was just that in directing attention to the import of ultimate consequences they wound up undermining the relevance of those most precious to their own.

Consolidating Familial Power

Anthony A. Volk
Department of Child and Youth Studies, Brock
University, St. Catharines, ON, Canada

Synonyms

Alloparenting
Family; Kin selection; Nepotism; Solidarity

Definition

In this context, consolidating family power refers to how adoption can help individuals support their kin and/or expand their familial social and economic resources.

Introduction

An important goal of evolutionary fitness is to ensure the passage of one's genes into future generations, including copies of one's genes that

are present in relatives (Hamilton 1963). One obvious way of doing this is to invest in one's own offspring so as to ensure the success of their shared genes (Trivers 1972). But parents can also increase their fitness by investing in copies of genes that reside in related, or even unrelated, children (Silk 1990; Volk 2011). There are two primary mechanisms at work under these circumstances: improving the success of non-offspring kin (kin selection) and improving familial access to social and/or economic resources (reciprocal altruism). These mechanisms are not necessarily exclusive of each other in enhancing familial power.

Kin Selection

Throughout history, raising offspring has been a challenging endeavor (Hrady 2011). Due to high mortality levels associated with adult lives (Volk and Atkinson 2008), the possibility of parents dying was quite real. In these cases, if the children were not of an age where they could independently support themselves (likely adolescence or beyond), those children would require substitute parental care (or alloparenting) in order to survive (Hrady 2011). Indeed, adoption of kin in contexts where the parents are still alive, but impoverished and/or incompetent, is found in many cultures including: modern Western countries, Brazil, and Peru; ancient Rome, medieval Europe, and Imperial China; and the Inuit, !Kung, Oceanic cultures, and West African cultures (Volk 2011). Thus this practice persists in modern cultures, in historic cultures, and in hunter-gatherer/agriculturist cultures. The benefits are relatively obvious as related by Hamilton (1963), such that investing in one's kin is beneficial so long as the net benefit to one's own genes (i.e., the costs to one's personal genes versus the benefit to shared kin genes) is positive. For example, a wealthy parent may face diminishing returns in continuing to invest in their own offspring versus investing in the offspring (i.e., nieces and nephews) of much poorer brother or sister. Finally, adoption may be a means

of promoting a family line when an adult lacks suitable offspring of their own due to infertility, death, and/or an inability to carry on the family lineage (e.g., Davis 2006).

Reciprocal Altruism

Another explanation for adopting kin or non-kin is reciprocal altruism. In this context adoption may be a way of securing economic assistance from the biological parents and/or adopted child (Demian 2004; Halbmeyer 2004). A relatively common arrangement is for the adopting parenting to care for a child when they are young and in return obtain labor and financial compensation from that child when they are older (Demian 2004). This arrangement is one way for wealthy adults to parlay their resources into benefits to their own genes at the expense of non-related genes.

Another form of reciprocal altruism that benefits the family is adopting for political or socially strategic reasons. These typically revolve around arranging future marriages and/or ending violent disputes (Halbmeyer 2004; Volk 2011). In these cases, the presence of the non-kin in the adopted family acts as a brake toward violence (e.g., adopting the son of one's enemy reduces their incentive to attack oneself) and/or as a catalyst toward marriage (e.g., adopting the daughter of an enemy or social rival increases their incentive to cooperate with you by arranging future marriages).

Conclusion

Adoption is a complex behavior that has roots in both reciprocal altruism and in kin selection. In either case, it can represent a significant benefit for the adopting family to expend resources in distantly related or unrelated children. The versatility of adoption in exchanging social and material resources for enhanced genetic fitness suggests that it was likely a widespread and viable

evolutionary strategy for promoting and consolidating familiar power.

Conspicuous Consumption

Gianni De Fraja

University of Nottingham, Nottingham, UK
 Università di Roma "Tor Vergata", Rome, Italy
 C.E.P.R., London, UK

Synonyms

[Ostentatious consumption](#)

Definition

The acquisition of goods or services which have no purpose other than to display the possessor's ability to possess them.

Introduction

The Russian billionaire Roman Abramovich is said to have spent £285,000 for the purchase of the personalized car number plate "VIP 1". While for him this is a trivial sum, displaying it advertised his ownership of the car to potential vandals or, worse, to the international criminal community and therefore exposed him to some increase in personal risk. The benefits that outweighed this increase in risk are not immediately obvious. Surely not an improvement in the comfort or the performance of the car, which are clearly unaffected by the symbols on the plates, a remaining possible motive is the intention to inspire awe and admiration in those who understand the rarity and expensiveness of this object: conspicuous consumption

Thorstein Veblen

While the concept of conspicuous consumption goes back at least to John Stuart Mill (1848), Veblen's theory of the leisured class gave a solid conceptual foundation to this idea. His books are rich in examples. "The chief use of servants is the

evidence they afford to the master's ability to pay," rather than helping him in any useful manner (Veblen 1899, p. 62). Their cumbersome liveries and unwieldy uniforms are actually designed to prevent them from performing any useful or productive activity. Similarly, skirts persist tenaciously as fashion accessories because, not despite, they "hamper the wearer at every turn and incapacitate her for all useful exertion," thus unmistakably demonstrating that she does not need to work (p. 171). Corsets and top hats are among his other examples. The ostentation of these goods is intended to demonstrate that the owner has no need to spend time and energy pursuing the necessities of life. As Frank notes (2007, p. 30), understanding the principles of conspicuous consumption may provide strong clues to *prima facie* inexplicable quirky regularities of modern life, such as the different way men's and women's garments are buttoned. Like many things, buttons first appeared as a luxury, and displaying them had therefore an ostentation value, and they did appear at a time when wealthy men would carry swords and wealthy women would be dressed by their servants. Also, at the time when right-handedness was the (often forcibly enforced) norm. Unsheathing a sword worn on the left hip with the right hand would risk having the hilt caught by the fold of the jacket, if the latter had a women's button style. Conversely, a right-handed maid would find it easier to button her mistress' garment given the way the sides are buttoned. The position of buttons for men's and women's clothes was therefore the natural choice, and once a pattern is established and there are no strong reasons to change it, it persists by inertia.

The desire for conspicuous consumption is by no means exclusive to the western leisure class of the turn of the nineteenth century. While, as noted by Piketty among others (Piketty et al. 2014), the extremely rich nowadays work much harder than their predecessors, their pattern of consumption has changed only due to changes in technology: the 70-hour a week investment fund manager who collects expensive watches, drinks fine wine, and drives supercars is much more widespread than miserly Scrooge-like individuals. Economists have investigated the features of preferences that

allow the emergence of the Veblen effect, the willingness to pay more for functionally equivalent substitutes (Bagwell and Bernheim 1996): from diamond-studded smartphones and cufflinks to cruises to Antarctica or the outer space in addition to the Titanic style ones also available a century ago. The last example illustrates that to play their display role, items of conspicuous consumption, unlike diamonds, need not be forever. In fact, in societies where storage and security of durable goods might be a problem, these are replaced by the ostentatious destruction of perishable or vulnerable commodities, such as chiefs wastefully burning immense quantity of precious oil, in ceremonial feast among some Native American population (the so-called potlatch; similar events occur in New Guinea and among the Maori, the Koha, the Kula, the Moka; Ridley 1996, p. 122). That conspicuous celebrations become more so as the information about individuals' status becomes less reliable has been shown to be the case by Bloch et al. (2004) in their empirical analysis of wedding celebrations in rural India.

Going back in time much further, the widespread prevalence of the importance of decorative visible items unnecessary or even harmful to survival among preindustrial societies (Murdock 1967 and Murdock and White 1969), as well as the ease with which western explorers could acquire the friendship and trust of the indigenous leaders with trifles and other cheap but rare objects, suggests that the desire for conspicuous consumption is a universal trait of human behavior and has therefore been hardwired in the brain since before the dispersal from Africa 80,000 or so years ago. One of the earliest and most intriguing examples is hand axes, manufactured for over a million years. These axes are knapped in a highly symmetrical shapes and polished well beyond the necessity of practical use for butchering or hunting; and they are indeed often found unused and in large hoards (Kohn and Mithen 1999).

Conspicuous consumption is not only not exclusive to modern humans, but it is not exclusive to humans at all, with some evidence, in many animal species, of powerful males obtaining

and protecting large territories, much larger than it can be possibly be necessary to provide food and shelter to the family and subordinate individuals (Zahavi and Zahavi 1997, pp 28–29).

Status, Conspicuous Consumption, and Sexual Success

This universality of the desire for items of conspicuous consumption opens the question of its benefit to individual humans. Veblen (1899) identified a correlation between conspicuous consumption and a person status, defined loosely as the esteem in which society holds a person. Conspicuous consumption of goods such as luxury goods, which are “completely novel in evolutionary terms,” enhances status, and that desiring status is evolutionary hardwired to affect directly an individual's utility (Robson 2001, p. 24). Thus, in this literature, conspicuous consumption is seen as a way to achieve status, with the prevalent behavior being snobbism (attempting to display rare and unusual items, as theorized by Mason, 1981) or conformism (attempting to display items that indicate appurtenance to a group membership of which is hard to obtain). Corneo and Jeanne (1997) identify the number of consumers in society as one of the determinants of whether the desire for conspicuous consumption determines snobbism or conformism.

Of course attributing the universal desire for conspicuous consumption to the quest for status simply shifts the question. Why is status desirable? Given the ubiquity across time and cultures of this desire, this question can be reformulated more rigorously as “what is the evolutionary advantage of having a high social status?” If genes that make their bearer desire status, even at the potential cost in terms of reduced survival opportunities, as the time and effort spent acquiring conspicuous items are time and effort subtracted to survival activities, such as finding food and shelter, are to become established, then they must also confer some evolutionary advantage. It is widely recognized that status increases the availability and the quality of sexual partners and therefore confers a reproductive advantage

that might more than compensate for the survival costs incurred while trying to achieve status.

De Fraja (2009) is one of the papers that side-steps status and suggests that conspicuous consumption could emerge as a direct mechanism enhancing a personal reproductive success. The mechanism is the same as that proposed by Zahavi (1975) and described in detail by Miller (2009) and formalized by Grafen (1990): conspicuous consumption is a signal that members of one sex use to indicate to potential mates that they possess unobservable characteristics which are valuable to members of the opposite sex. To the extent that the ability to acquire items suitable for conspicuous consumption correlates with an individual quality as a parent, either because of a better genetic make-up or because it suggests the ability to provide food and shelter for children, choosing partners who can indulge in conspicuous consumption enhances fitness. The mechanism is essentially identically to that posed by Williams: “it is to the female’s advantage to be able to pick the most fit male available for fathering her brood. Unusually fit fathers tend to have unusually fit offspring. One of the functions of courtship would be the advertisement, by a male, of how fit he is. A male whose general health and nutrition enables him to indulge in full development of secondary [not physiologically necessary for reproduction] sexual characters [...] is likely to be reasonably fit genetically [...] In submitting only to a male with such signs of fitness a female would probably be aiding the survival of her own genes” (Williams 1966, p. 184). The hand axes mentioned above are a very apt instance of this, as well as being the earliest documented: the ability to manufacture these axes is a clear indication of dexterity, a genetic trait likely to be highly valued in potential mates (Kohn and Mithen 1999). The inherent danger in the activity, in an age where losing an eye or a finger seriously impaired a person’s survival chances, highlights the trade-off between survival and reproduction underlying the signaling theory of sexual selection: possession and display of many hard-to-make hand axes says to potential sexual partners “You should want my genes, because I am good with my hands, for me the risk of accidentally chopping a finger or losing an eye from a splinter is so low that it has

never happened, even though, as you can see, I spend a lot of time making these useless axes. And being good with their hands is something that you should want your offspring to be.” In modern days, Buss’s team systematically analyzed lonely heart columns and conducted surveys in 37 different societies and amply demonstrating how women prefer wealth in men, when men prefer youth in women (Buss et al. 1990). Ridley (2003, p. 54) argues that “men seek wealth because they know it attracts women,” as exemplified by Aristotle Onassis’s dictum that “if women did not exist, all the money in the world would have no meaning.” In her analysis of Murdock and White (1969) data, Betzig (1986) finds that “power predicts the size of a man’s harem” and wealth is a very good indicator of power. On the other hand, status and conspicuous consumption are not the only way to increase mate access: cultural displays may also play this role (Miller 1999), and Zahavi and Zahavi’s (1997, pp. 143 ff.) observe that, in some species, such as the birds known as Arabian warblers, prestige, as opposed to mere rank, determines the group’s dominant male’s degree of exclusivity of access to females.

Conclusion

In order to serve as a signal either to provide evidence of a more valuable genetic make-up or to establish status, the items a person displays need to be more valuable, rarer, and harder to acquire than those that are more easily available to the other members of society. This suggests that relative, rather than absolute, consumption should constitute the signal and hence valued by individuals, as argued long ago by Duesenberry (1949): we need to have more than our neighbor to be attributed a higher status. This has two consequences. Firstly, it pushes society in a rat race, with everyone having to run fast simply to “keep up with the Joneses.” It is a prisoner’s dilemma, whereby, if everyone were to reduce their consumption in the same proportion, everybody would be better-off, having the same relative position but with fewer of the costs (effort, risk, time) associated with the acquisition of items of conspicuous consumption, but from

each individual's viewpoint, acquiring more such items is beneficial because it enhances that individual's status. Evidence for the relative consumption hypothesis is mixed, however, whether from surveys (Maurer and Meier 2008; Kuhn et al. 2008) or from experimental evidence (Alpizar et al. 2005). Arrow and Dasgupta (2009) reconcile this evidence with the importance of relative consumption, by considering the role of future relative consumption.

Secondly, if individuals are willing to pay for items of no intrinsic value, then the structure of the optimal taxes in an economy, that is, of the taxes that minimize the loss of welfare of a country's citizens subject to raising a minimal level of income, is altered. If there are Veblen effects, that is, if the willingness to pay for a luxury item increases with the cost of the item, then adding to the cost with a tax also increases the consumer's willingness to pay, that is, the utility of owning it, so taxes can be raised without a corresponding reduction in welfare (Ng 1987). John Stuart Mill's preference for taxation of luxury goods was probably based on a mechanism of this kind. The structure of the optimal income tax is also changed when consumers care for status (Ireland 2001), with more emphasis for redistribution if the rich care more for status than the poor.

Conspicuous Consumption (Marketing and Economics)

Manfred Hammerl and Carina Kradischnig
University of Graz, Graz, Austria

Synonyms

Flashy consumption; Ostentatious consumption

Definition

Conspicuous consumption is the public consumption or usage of costly goods, services, or leisure activities out of the conscious or unconscious motive to display or enhance one's own social status, to indicate one's ability to pay for it and hence displaying one's own wealth despite the possibility to consume cheaper alternatives which yield the same functionality. So in principle conspicuous consumption is unnecessary (and often wasteful) consumption from a rational point of view which does not satisfy basic economic needs.

Introduction

Conspicuous consumption is not a new phenomenon. It probably has existed since humans use goods (e.g., cloth, weapons, music instruments). Remember the use of very expensive and hard to produce colorant purple by ancient roman

emperors or the luxury displayed publicly by most other aristocrats throughout our known history. But it was Thorstein Veblen's (1899) merit to provide the term *conspicuous consumption* by writing his analysis of the leisure class more than 100 years ago. All research in consumer behavior on this topic still refers back to Veblen's work although some scholars argue that it is indeed often cited but rarely read. While still at Veblen's times – and anymore in the ages before – conspicuous consumption was merely a phenomenon among the rich, industrialization, increasing prosperity for broader parts of the population, and the rise of the middle class lead to a spread of conspicuous consumption behavior in the century after Veblen.

Throughout the twenty-first century conspicuous consumption often was regarded to be irrational consumer behavior (cf. Shukla 2008). Homo economicus would not engage in conspicuous consumption, maybe that's why economists struggle to understand such behavior in its full depth. Mason (1984), who has also written two books (1981, 1998) on conspicuous consumption, provided a literature review about explanatory models for conspicuous consumption. His analysis of social psychological and rational economic models resulted in two points: (a) economists have not contributed much to a better understanding of conspicuous consumption up to that time, and (b) he suggested to utilize more psychological models in combination with economic ones to gain deeper insights. A more recent paper from Mason (2000) again criticizes economists' omission of extensive research on conspicuous consumption. His main objective for today's economy and politics is to find a way to stem the problem of wasteful consumption that comes hand in hand with mass conspicuous consumption behavior as well as to put our resources into "more productive economic activity" (Mason 2000, p. 123).

But at least one often used concept in consumer behavior research originates from economic research in the mid of the twenty-first century. Leibenstein (1950) coined the term *Veblen Effect*. This means that not only the quality or functionality of any product constitutes its value but also

its price. As a consequence products become more interesting for people who want to display their status through conspicuous consumption when their price rises – when the price falls (the product remains exactly the same) interest is decreasing. And Leibenstein made another explanatory note on the *Veblen Effect*: Indeed it will not be the price actually paid for a product that counts but instead the price, other people (the perceivers of the signal, the relevant reference groups, etc.) think was paid for the product. Such reflections will help to understand why today in wide parts of the world counterfeit products and branded goods are so often consumed.

In marketing probably a bit more research on conspicuous consumption was conducted (see next section). But within this field – not so in economics – several terms, such as prestige consumption, luxury consumption, and most often status consumption, are used similarly or sometimes even synonymously for conspicuous consumption. This may be due to the fact that there is no distinct definition of conspicuous consumption in the literature. Anyhow, such practice is not wise as some scholars note. Admittedly there is some overlap, but basically status consumption and conspicuous consumption are found to be two different constructs (cf. the discussion in Shukla 2008, pp. 26–27). Unfortunately also the relationship between these two constructs is unclear to some extent. While some scholars argue that one engages in conspicuous consumption first and then gains status, others have the opinion that it is the other way round.

Contemporary Research on Conspicuous Consumption in Consumer Behavior

In the twenty-first century, we notice that traditional consumer behavior research and evolutionary psychology are approaching each other which yields deeper insights and a more complete understanding of consumption phenomena. Geoffrey Miller and Gad Saad were among the first and most prominent scholars who analyzed marketing issues from an evolutionary point of view. Both have excellent chapters on conspicuous

consumption in their principal consumer behavior books *Spent* (Miller 2009) and *The Evolutionary Bases of Consumption* (Saad 2007). For Miller (2009, and Saad 2007 too) it is obvious that engaging in conspicuous consumption is a means of signaling fitness in the context of sexual selection. Referring to costly signaling theory the (high) price of a product is considered a benefit (and not a cost) in the context of conspicuous consumption. Not a small number of recent studies share this view of conspicuous consumption as a form of costly signaling.

To be regarded as a costly signal, a signal has to meet four criteria (cf. Nelissen and Meijers 2011). The signal (a) has to be easily observable by others, (b) has to be difficult to fake by others because of its high costs, (c) has to be associated with unobservable but desirable qualities of the signaler, and (d) has to entail some fitness benefit in the end. (a) and (b) could easily be fulfilled by publicly consumed expensive goods. (c) could indirectly be fulfilled since consuming such high-priced goods requires a certain level of wealth which may be acquired due to hard work, intelligence, competitiveness, long phases of good health in life, etc. Finally (d) is admittedly difficult to measure but could also be approached as shown by Nelissen and Meijers (2011) in the context of social interactions. So conspicuous consumption indeed could be regarded as costly signaling in an evolutionary sense.

Following Saad (2007) conspicuous consumption clearly has evolutionary roots. It is an universal and innate phenomenon. He discusses several empirical findings to underpin this point, among others the – from a traditional rational point of view – irrational fact that even poor people in all parts of the world try to enhance their status by engaging in conspicuous consumption (e.g., luxury apparel, watches, cars) although they cannot really afford it and should better invest their money in their daily needs. Often this ends up in buying and using counterfeit products (a topic of increasing importance in marketing and economics) to at least give the impression of being wealthy and having status. Understanding that acquiring and displaying status is a relevant human need leads to the conclusion that

conspicuous consumption is in principle not a typical irrational behavior (as older literature suggests) but a manifestation of some deeper (evolutionary) rationality.

Over the last years some lines of research in consumer behavior have emerged which are informed by evolutionary theorizing. To a great part that research focuses on intra- and intersexual competition. Among others Henninghausen et al. (2016) found that conspicuous consumption is a means for men to signal and enhance their status in intrasexual competition. Another male is a potential rival who should be outdone. The like was found for women (cf. Wang and Griskevicius 2014). Women engage in conspicuous consumption to signal other women that their actual partner shows high commitment to them (he cares for his wife, especially financially. A similarity to Veblen's (1899) vicarious consumption is evident). This is particularly valuable to prevent potential mate poaching by female rivals. Regarding intersexual competition, there is very interesting research such as a series of studies from Griskevicius et al. (2007). When mating motives are triggered both, men and women, tend to enhance their status and mate value by publicly engaging in conspicuous behavior. But differences occur in the way they do so. While men tend to increase their consumption of luxury goods, women tend to increase altruistic helping behavior. Private consumption (men) or private altruistic behavior (women) was not affected. So alongside the term conspicuous consumption, we may call this public altruistic behavior of women conspicuous altruism – it also qualifies as costly signal.

Further remarkable findings came from research on social benefits of conspicuous consumption. Nelissen and Meijers (2011) and others found that wearing luxury apparel results in more positive attributions from others and in preferential treatments in everyday social interactions. Surprisingly it also leads to the economically irrational fact that fundraisers on the streets receive more money from passersby when wearing luxury apparel than by wearing ordinary apparel (cf. Nelissen and Meijers 2011). And finally

there is research on so-called green consumption. Griskevicius et al. (2010) found that choosing green products may be due to status motives. When such products are costly and could be consumed in public (e.g., an ecofriendly but expensive Tesla car), they are best suited to display conspicuous altruism (the signaler shows that he cares for the environment AND can do so by using a really expensive product).

As a last point two small research streams in the field of marketing should be mentioned. As most concepts in marketing, scholars also want to measure conspicuous consumption in consumer behavior questionnaires. While most scales in that context were actually constructed to measure status consumption, Chaudhuri et al. (2011) developed an “11-item Conspicuous Consumption Orientation Scale.” They regard conspicuous consumption orientation as an “innate trait level, individualistic variable that motivates consumer to engage in visible forms of consumption in order to exhibit their uniqueness, as expressed through product selection and usage” (Chaudhuri et al. 2011, p. 217). Other marketing scholars found some changes in conspicuous consumption behavior by identifying *inconspicuous consumption* (Eckhardt et al. 2015), also known as subtle consumption. To some degree they attribute this shift – at least in wealthy industrialized parts of the world – to economic crises. Some consumers probably do not want to stand out to far from their community by engaging in ostentatious consumption. Implications for luxury brand manufacturers are, for example, to reduce their logo size on apparel. But the truth is that someone somehow must recognize what is worn – otherwise it probably won't make sense anymore to buy a more expensive product. The reference group will notice, and that is what it is all about in conspicuous consumption.

Conclusion

Present-day research taught us that conspicuous consumption is not the irrational behavior it once was considered to be but instead is basically an

evolutionary rational behavior. As Geoffrey Miller (2009) wrote, over the past 1000 years we have learned that we can display desirable traits by buying and consuming goods and services. Of course today's globalized market economy and consumer society could lead to maladaptations. All the more we should be sensible to the evolutionary roots of our consumer behavior.

Domain specificity; Functional fixity

Definition

The processing system and cortical correlates of encoding, storage, and recollection of learned information differ with the content of memories.

Introduction

Evolutionary processes cause each of multiple memory systems specialized to some degree, shaped by natural selection, to solve the adaptive problems posed by the environment which other memory systems cannot deal with. Humans have at least two qualitatively different systems of recollection based on the content, namely, declarative memory system and nondeclarative memory system. Declarative memory refers to the conscious storage and retrieval of information, and it can be declared by language, while nondeclarative memory involves implicit learning of skills, priming, and association (Squire 1992; Squire and Zola 1996). Declarative memory can furthermore be differentiated into two subcategories: episodic memory and semantic memory. Episodic memory is the memory of events, times, places, and associated emotions related to specific events, while semantic memory refers to the memory of concept-based knowledge independent of context and event (Tulving 1972). The taxonomy of memory systems provides an insight of functionally specialized, content-specific memory systems.

Biological Evidence of Content-Specific Memory

The study of functionally distinct cortical regions of recollection was first found in amnesic patients with brain damages. For example, the most-studied amnesic patient H.M. whose medial temporal lobes, especially the hippocampus, were removed can still learn new skills, but he cannot encode new episodic memories (Milner et al. 1968; Sherry and Schacter 1987). This lent the credence of two distinct memory systems (Squire 2009; Corkin 2002; Squire and Wixted 2011). Later on, the amnesia and animal studies found that the declarative memory largely depends on the medial temporal lobe (MTL) and its associated structures to encode and retrieve the information while nondeclarative memory system is independent of MTL (Squire 1992, 2004; Squire et al. 2004; Reber 2013). Additionally, the empirical

experiments conducted by Tulving and Thomson (1973) found episodic memory and semantic memory differ in encoding process, but not in retrieval process. The impairment of frontal cortex is related to the failure of encoding episodic memories (Janowsky, Shimamura and Squire 1989).

A growing number of neuroimaging and animal studies have investigated the cortical underpinning of recollection and provided strong evidence that the storage of different contents is associated with the activity in functionally distinct cortical regions. As for declarative memory, previous studies have found Wernicke's area for words (Wise et al. 1991) and distinct temporal cortices for memories of objects and faces (Wallis and Rolls 1997), showing that functional specificity exists in remembering different visual images. There are also pieces of evidences that brain-damage patients have content-specific deficits of lexical knowledge. For instance, patient M.D. cannot name fruits and vegetables but has no problem in naming animals (Caramazza and Shelton 1998). Meanwhile, the long-term storage of nondeclarative information is found associated with the cerebellum, basal ganglia, motor cortex, and premotor cortex (Reber 2013).

Adaptationism

In most memory studies, the stimuli that have emotional valence or adaptive importance are avoided (Klein et al. 2002). This experimental design does not take into consideration that our memory systems are designed to store the information which is critical for survival, such as offspring (Kendrick et al. 1992), the locations of food (Hampton et al. 1995; Hampton and Shettleworth 1996), environmental threat (Mineka and Cook 1993), and mating (Crews and Moore 1986). The content specificity of memory systems exists to permit encoding and retrieving appropriate content of memory efficiently in response to the adaptive demands from the environment (Tulving and Thomson 1973). Animals and humans, for instance, tend to avoid food which make them sick before. Semantic memory stores the extracted

invariant features from a series of events, whereas episodic memory has detailed information of an event. As Klein and his colleagues (2002) have mentioned, depending on the task, retrieval of memory can pull up content-specific information from episodic memory or semantic memory alone or both of these two memory systems.

Conclusion

Therefore, the content specificity may imply that multiple memory systems underwent distinct evolutionary paths and are designed to serve distinct functions (Sherry and Schacter 1987). The content specificity has its advantages. It can expedite information accessibility (speed) and retrieve relevant information to deal with the current task (accuracy) in multiple memory systems (Klein et al. 2002).

Introduction

There is a widespread misunderstanding among social scientists that evolved psychological

adaptations are like reflexes or “instincts” – blind, inflexible, and insensitive to social and environmental circumstances. Nothing could be further from the truth. Evolved psychological mechanisms are environmentally sensitive and exquisitely context-dependent.

The purpose of this entry is to introduce the reader to the centrality of context in evolutionary psychology. To this end, we discuss: (1) the theoretical importance of context in evolutionary psychology, (2) the nature of evolved learning mechanisms, and (3) specific examples of context effects in evolutionary psychology.

The Importance of Context in Evolutionary Psychology

Environmental context plays a key causal and explanatory role in evolutionary psychology. Adaptations – the primary products of natural selection – require environmental input at every stage of their emergence. Indeed, environmental pressures (1) drove the evolution of the adaptations in the first place, (2) play a key role in their ontogenetic development, and (3) are responsible for activating them in the present (Buss 1995; DeKay and Buss 1992). In other words, adaptations evolve because of environmental challenges in the first place, they require specific kinds of environmental input to develop properly across an organism’s lifespan, and proximate contextual input triggers their activation in the immediate present. Far from neglecting environmental context, an evolutionary perspective places it center stage.

Another way to see the centrality of context in evolutionary psychology is by considering two facts: (1) the brain evolved to extract information from the environment and use that information to regulate behavior, and (2) different contexts carry different information. Context is central in evolutionary psychology not only in the sense that different contexts present different adaptive problems, but, crucially, environments also *carry the information needed to solve those problems*. Stated differently, an organism’s brain – its evolved on-board computer – must monitor the

environment for information relevant to the survival and reproduction of the organism.

In sum, context occupies center stage in evolutionary psychology for two broad reasons. First, adaptations require environmental input at every stage of their development, from initial evolution to current activation. And second, for an evolved information processor, context is central because it simultaneously poses key adaptive problems and carries the information needed to solve those problems.

Evolved Learning Mechanisms

There is a widespread misconception that “evolved” and “learned” are competing explanations. It might intuitively *seem* that “evolved” is the opposite of “learned,” but this is dead wrong. These two kinds of explanations are not in conflict for two reasons.

First, they answer distinct questions at complementary levels of analysis. Learning explanations are at the *proximate* level of analysis, whereas evolutionary explanations usually begin at the *ultimate* level of analysis (see Alcock 2012; Tinbergen 1963; Lewis et al. 2017, for a discussion of the relationship between ultimate and proximate levels of analysis).

Second, *learning* requires *evolved learning mechanisms* instantiated in the brain. This is why a brain can learn things a cauliflower cannot: the brain is equipped with evolved learning mechanisms but the cauliflower is not (Tooby and Cosmides 2015). Similarly, if you try to teach a young dog and a human child the same material in the same way, they will learn different things. This is because the puppy’s brain and the child’s brain are equipped with different learning mechanisms. Far from being in conflict, evolution and learning are explanatory partners. To explain psychological and behavioral outcomes, you often need to invoke both evolution and learning in the form of evolved learning mechanisms.

Specific examples of evolved learning mechanisms illustrate this point. Three prominent examples are (1) food aversion learning, (2) specialized fear learning, and (3) incest aversion learning.

An example of food aversion learning is the Garcia Effect, which refers to the discovery that rats will readily learn to associate nausea with food, but not with lights or sounds (Garcia and Koelling 1966). The Garcia effect occurs because in rats' natural environment and across their evolutionary history, nausea was caused by toxic or pathogenic food but not by lights or sounds. This phenomenon demonstrates that rats have evolved to learn some things (the relationship between nausea and food) more easily and more readily than others (the relationship between nausea and buzzers).

Specialized *fear learning adaptations* are common among primates. Fear learning in monkeys is a good example. If an observer monkey watches a target monkey react to a snake with fear, the observer monkey will learn a fear of snakes easily and rapidly – sometimes even in a single trial (Mineka et al. 1984). By contrast, if an observer monkey watches a target monkey react with the same fear to a rabbit or flowers, the observer will usually fail to learn a fear of rabbits or flowers. Monkeys are biologically prepared to learn a fear of snakes, but not of rabbits and flowers. It is also harder to get them to *unlearn* it: it is more difficult to extinguish a fear of snakes than a fear of rabbits or flowers (Cook and Mineka 1990). This “biological preparedness” supports the view that organisms are not equipped with a single, all-purpose learning mechanism. Rather, species have evolved problem-specific learning mechanisms that are specialized for learning information relevant to the particular adaptive problems they encountered over the course of their evolution. Species that have no evolutionary history of being preyed upon by snakes, for example, have not evolved this specialized fear learning mechanism.

Human also have specialized fear learning adaptations for snakes, spiders, heights, darkness, and strangers, but not for evolutionarily novel hazards such as cars, carcinogenic food additives, and cigarettes – despite the fact that these are more dangerous and kill more people in modern environments (Marks and Nesse 1994).

Incest aversion learning differs from both food aversion learning and fear learning adaptations –

in the adaptive problem it solves, the environmental input by which it develops, and in the information-processing machinery that produces its behavioral output. The adaptive problem in this case centers on avoiding mating with close genetic relatives. But humans are not born knowing who their genetic relatives are – this information must be learned. Incest avoidance mechanisms appear to take in at least two key inputs from the environment during development: (1) co-residence during childhood, and (2) maternal perinatal association (if you are the older sibling, seeing your mother breastfeed the other child). To simplify the process, if the mechanism in question receives sufficient levels of these inputs (e.g., shared habitation, observing a child nursing from one's own mother, etc.), it tags the co-resident as a sibling or other close kin and produces a lack of sexual attraction to that person as well as disgust at the mere thought of having sex with that person (Lieberman et al. 2007; Westermarck 1891). On the other hand, if the evolved learning mechanism *does not* receive sufficient levels of these two key inputs, it does not tag the other individual as a sibling and does not produce incest aversion toward that person. This is how we avoid having sex with our genetic relatives – through a learning mechanism that evolved because of its adaptive value in preventing inbreeding depression (Lieberman et al. 2007; Rantala and Marcinkowska 2011; see Al-Shawaf et al. 2018, for a discussion of the significance of these findings with respect to a key misconception about evolution and behavior).

Food aversion learning, hazardous fear learning, and incest avoidance learning all illustrate the importance of evolved learning mechanisms. These examples highlight the key point that for two reasons, evolution and learning should not be thought of as separate processes in zero-sum competition with each other for explanatory power. First, learning requires *evolved learning mechanisms* instantiated in the brain. Second, evolution and learning offer answers at different levels of analysis – ultimate for evolution and proximate for learning. There is no necessary conflict between the two (see Lewis et al. 2017).

Context Effects in Evolutionary Psychology

Specific empirical examples help to illustrate the centrality of the environment in evolutionary psychology. This section details context effects in four areas of evolutionary psychological research: emotions, cooperation and altruism, lifespan development, and human mating.

Some theorists draw a distinction between *context* effects and *condition* effects, emphasizing that context refers to the external environment, whereas condition refers to the internal environment (an organism's psychophysiological state). However, there is no fundamental distinction here: the external and internal environment are both critical to survival and reproduction, and evolved psychological mechanisms are sensitive to both. Broadly conceived, the terms "environment" or "context" therefore include elements of the ecological environment (e.g., parasite type and prevalence, flora and fauna, dangers from drowning), the social environment (e.g., local sex ratio, cultural norms about mating), and the internal environment (e.g., an individual's mutation load, strength of immune function). We touch on all three.

Emotions

Evolutionary psychological thinking suggests that emotions are heavily context-dependent, and that this context-dependence is systematic and predictable rather than arbitrary and random.

Disgust provides a good example. An adaptive disgust system would be designed to respond to pathogen-dense environments by downregulating personality traits such as extraversion and openness to experience. This would have the effect of reducing exploratory behaviors and intimate interactions with others, thereby decreasing the likelihood of infection. This is exactly what studies find: priming people with pathogen salience makes them regard themselves as less extraverted and less open to experience, while also prompting avoidant motor behavior (Mortensen et al. 2010). Experimentally inducing disgust reduces people's desire for short-term mating (Al-Shawaf et al. 2018). Cross-cultural data show a similar pattern:

people who live in regions of the world with higher pathogen density tend to be lower in extraversion, openness to experience, and proclivity for short-term mating (Schaller and Murray 2008). Research motivated by the hypothesis that masculine facial features are indicative of immunocompetence has shown that women who are more concerned with pathogens and disease show a heightened preference for masculine faces (DeBruine et al. 2010). Research based on the idea that out-group members tend to carry novel diseases that the immune system is not prepared to deal with suggests that priming people with the context cue of disease salience makes them more xenophobic (Faulkner et al. 2004). The contextual variable of pregnancy status affects levels of disgust in a principled and functional way, preventing the mother from ingesting teratogens that could harm the developing fetus (Fessler et al. 2005; Profet 1992). Studies show that mothers find their own baby's feces less disgusting than other babies' feces (Case et al. 2006). Finally, evolutionary analyses of disgust suggest a host of novel context-based hypotheses (Al-Shawaf et al. 2016; Al-Shawaf et al. 2017). These examples all highlight the context-sensitive nature of disgust: this emotion is designed to adjust our psychology, physiology, and behavior in response to different contextual cues in order to help solve the survival- or reproduction-relevant problem at hand.

Emotions such as anger show a similar pattern of context-sensitivity. For example, the welfare-recalibration theory of anger posits that an organism gets angry when it detects that another individual has not placed sufficient emphasis on its welfare. The victim then displays anger in an attempt to "convince" the perpetrator to upregulate the value that he places on the victim's welfare (Sell et al. 2009). Just as this welfare-recalibration theory suggests, the contexts that trigger anger are systematically predictable: people react with more anger when they have suffered a large cost, when the perpetrator only gained a small benefit, and when the perpetrator knew exactly whom he was harming. Relatedly, when a victim discovers wrongdoing, the perpetrator typically attempts to defuse the victim's

anger in a predictable manner: by asserting that the benefit he reaped was large, that he didn't realize how large the cost to the victim was, and that he didn't know exactly whom he was harming with his behavior (Sell et al. 2017). Finally, precisely as the theory predicts, context and condition affect individual differences in anger: more attractive women – and more attractive and more physically formidable men – anger more readily than their less attractive and less formidable counterparts (for a discussion of the logic underlying these predictions, see Sell et al. 2009).

The key point here is that an evolutionary psychological approach to the emotions emphasizes their context-dependence. Human emotions are activated by specific contexts, and these emotions subsequently regulate aspects of cognition, perception, physiology, and behavior in ways that are functional precisely because they match context. This is true not just of disgust and anger but also of pride (Sznycer et al. 2017), shame (Sznycer et al. 2016), jealousy (Buss 2000), envy (Hill and Buss 2006), sexual arousal (Al-Shawaf et al. 2016), hunger (Al-Shawaf 2016), love (Buss 2006), and, to our knowledge, all emotions. These emotions are functional precisely because they are so context-sensitive.

Cooperation, Altruism, and Group Living

The domains of *cooperation and altruism* nicely illustrate the centrality of context in evolutionary psychology. Key contextual variables in this area of research include how problems are framed, audience effects, and kinship.

One classic finding in this area of research is this: people perform poorly on abstract logical reasoning tasks such as the Wason Selection task when the problem is framed in terms of abstract letters and numbers, but they perform exceptionally well when the same problem is framed in terms of social exchange and cheater detection (Cosmides 1989). Because we have evolved to detect cheaters and rule violators in social exchange, but not to solve abstract logic problems involving letters and numbers, our performance on the former is much better than our performance on the latter. The remarkable thing about these

findings is that the two problems are logically identical. Our vastly different performance is due to the architecture of our evolved psychological mechanisms in conjunction with a key contextual variable (in this case, whether the problem is framed in terms of letters and numbers or in terms of detecting cheaters; Cosmides and Tooby 1989). Similarly, because we evolved in an environment in which we had to solve problems involving *frequencies*, but not *probabilities*, we are much better at solving problems framed in a frequentist format than mathematically *identical* problems framed in a probabilistic format (Brase et al. 1998; Cosmides and Tooby 1996; Gigerenzer 1991). The key idea here is the same: our evolved psychological mechanisms are built to process some contextual cues – roughly, those that were ancestrally ecologically valid – but not others. As a consequence, these mechanisms can produce radically different outcomes because of a change in a single contextual cue.

Another key contextual variable in the domain of altruism and cooperation is the presence of an audience. Studies suggest that we are more altruistic in public than in private, and that we choose to engage in more effortful altruism when we are being watched compared to when we are not (e.g., Bereczkei et al. 2010). Research shows that we are keener to mete out moralistic punishments when other individuals in the group are likely to find out that we engaged in costly punishment (which benefits the entire group; Kurzban et al. 2007). Experiments on the evolved psychology undergirding our moral evaluations of others suggest that we like and trust people more when their moral beliefs appear deontological (rule-based) rather than consequentialist (outcome-based; Sacco et al. 2017). This, in turn, suggests a novel hypothesis: that people may tend to present themselves as more deontological when they are being watched than when they are alone.

Kinship is another contextual variable that plays a central role in people's altruistic behavior. We tend to help and bequeath our assets to kin more than non-kin, and to closer kin more than distant kin (Smith et al. 1987). People's preferred solution to the famous trolley problem changes

when the potential victims are kin (Bleske-Rechek et al. 2010). We are more willing to sacrifice our weekends and a day's pay to search for perpetrators who victimized kin as opposed to non-kin (Lieberman and Linke 2007). We prefer harsher punishments for offenders when the victim is a genetic relative, as we do when a rule violator victimized an in-group member as opposed to an out-group member (Bernhard et al. 2006; Lieberman and Linke 2007). By contrast, we prefer *lighter* punishments when the *perpetrator* is a genetic relative. We are also more likely to attribute remorse to the perpetrator when he or she is a genetic relative (Lieberman and Linke 2007). Kinship is such an important contextual variable that people try to influence non-kin to induce higher levels of cooperation by invoking kin terminology: *brothers* in arms, a sorority of *sisters*, the *motherland*, and so on (Daly et al. 1997; Salmon 1998).

In sum, cooperation and altruism point to the same conclusion as that of emotions: context is crucial – and deeply embedded in the fabric of evolutionary psychological thinking.

Development

Lifespan development also exemplifies the importance of context in evolutionary thinking. We present a few examples from childhood and adulthood.

In infancy and early childhood, fears (e.g., fear of strange males) come online at the developmentally appropriate time – approximately when the developing organism begins to confront the relevant adaptive problem (in this case, coming into contact with strange adult males; Boyer and Bergstrom 2011). Later during development, some evidence suggests that father absence may channel children toward a path that includes earlier puberty, earlier reproduction, a stronger proclivity for short-term mating, and less investment in long-term relationships (Belsky et al. 1991; but see Comings et al. 2002, for a different explanation). Relatedly, the context of a harsh and unpredictable environment in early childhood appears to channel individuals toward greater future discounting, a stronger tendency to value immediate rewards over delayed gratification, and

less investment in committed long-term mating (Ellis et al. 2009; see Barbaro et al. 2017, for a different view and a cautionary note).

Other developmental work suggests that maternal care during infancy affects the development of neural systems involved in fear and stress reactivity. For example, the brains of rat pups who receive grooming, licking, and arched-back nursing develop in ways that lead to greater stress resistance, less fearfulness, and less behavioral reactivity to stress-inducing situations (Caldji et al. 1998).

Studies suggest that personality traits such as extraversion may be predictable on the basis of developmental context effects. High levels of extraversion can lead to increased mating opportunities by initiating more interactions with potential mates and by forming new friendships and valuable social alliances (Nettle 2005, 2006; Denissen and Penke 2008). Because more attractive individuals are more likely to reap mating benefits from the social interactions associated with high levels of extraversion, we should expect selection to have favored extraversion-calibrating mechanisms that are sensitive to an individual's own physical attractiveness. Indeed, studies show that both men's and women's physical attractiveness predicts their extraversion levels (Lukaszewski and Roney 2011). Because mates and positions of high social status are contested resources, high levels of extraversion can also expose individuals to competition and conflict, in particular among men (Lukaszewski and Roney 2011). Consistent with this, physical strength predicts extraversion among men.

The centrality of context continues to manifest itself throughout the lifespan. Men downregulate testosterone production after entering into a committed relationship, and downregulate testosterone further after having a child (Burnham et al. 2003; Gray et al. 2006). These changes are functional, as reduced testosterone facilitates deeper commitment to one's mate, reduced aggression, and greater investment in parenting. Evolved psychological mechanisms are – and indeed must be – exquisitely sensitive to context.

Mating

Like emotions, altruism, and development, the psychology of mating is highly context-dependent. We describe several examples, first from men's mating psychology and then from women's.

Men's Mating Psychology

Men who are satisfied in their romantic relationships tend to show less attentional adhesion to attractive women (Miller 1997; Maner et al. 2008). By contrast, men who are less satisfied and men with a stronger short-term mating orientation demonstrate more attentional adhesion to attractive women (Maner et al. 2007).

The temporal context of mating – short-term or long-term – also affects a variety of male mate preferences. For example, men's preference for intelligence depends on mating context (stronger preference in long-term mating), as does their perception of promiscuity (desirable in short-term mating but undesirable in long-term mating; Buss and Schmitt 1993; Goetz et al. 2012). Men interested in short-term mating display a heightened emphasis on bodily attractiveness relative to men interested in long-term mating, whereas those oriented toward long-term mating display a heightened emphasis on facial attractiveness (the body contains more information about current fertility, whereas the face contains more information about long-term reproductive value; see Confer et al. 2010). And many preferences and standards shift when men are pursuing short-term mating instead of long-term mating (e.g., standards are lowered for a variety of qualities during short-term mating; Buss and Schmitt 1993). Researchers have even hypothesized that the return to (pre-arousal) baseline after orgasm is different for men oriented toward short-term mating than for those oriented toward long-term mating (Al-Shawaf et al. 2016).

Men's own qualities affect their mating choices and proclivities as well. For instance, men higher in mate value tend to reduce their parenting effort and invest more in mating (Hewlett 1991). By contrast, those lower in mate value tend to invest more heavily in parenting (Smuts and Gubernick 1992). One's mate

value or physical attractiveness may even influence one's preferred mating strategy (e.g., Al-Shawaf et al. 2015; Gangestad and Simpson 2000). Preliminary molecular genetic evidence suggests that men with longer CAG repeats at the androgen receptor locus (i.e., men with reduced sensitivity to testosterone) are more likely to interpret ambiguous cues as indicative of their mate's infidelity and react with greater emotional upset to such cues (Lewis et al. 2018).

Studies also suggest that merely being exposed to attractive women causes men to declare that they are more ambitious and more interested in accruing wealth and succeeding in their careers (Roney 2003). Similarly, the mere presence of attractive female observers causes male skateboarders to experience a rise in testosterone, take more risks, and have more accidents (Ronay and Hippel 2010). And research suggests that looking at pictures of attractive models leads men to feel less committed to, less interested in, and less serious about their own partners (Kenrick et al. 1994).

Women's Mating Psychology

Women's mating psychology is also highly context-sensitive. For example, women of higher mate value have higher mating standards, demanding higher minimum levels of various attributes in their partners (Buss and Shackelford 2008; Waynforth and Dunbar 1995). Similarly, women with higher incomes and higher levels of education display a heightened preference for income, career, and educational attainment in their mates (Buss 1989).

Women, like their nonhuman female counterparts, engage in *mate choice copying* – a phenomenon whereby women find a man more attractive if he is already mated (Dugatkin 2000; Waynforth 2007), especially if his mate is highly attractive and appears to be genuinely interested in him (e.g., Place et al. 2010; Waynforth 2007). That is, women appear to use the social-contextual input of other women's choices to process information about a man's likely mate value.

Women's specific mate preferences also appear to depend on mating context, with increasing interest in traits such as muscularity, masculinity,

confidence, physical attractiveness, and facial symmetry during short-term mating (e.g., Buss 2016; Gangestad et al. 2007; Li and Kenrick 2006; Provost et al. 2008). Relatedly, women's desire for extra-pair affairs is highly context-sensitive: it is primarily women whose partners lack hypothesized cues of good genetic quality who exhibit a desire for extra-pair copulations (Gangestad et al. 2005). Furthermore, when they do have affairs, women appear to specifically pick men who possess these attributes (e.g., facial symmetry, physical attractiveness; Gangestad and Thornhill 1997). Even women's competitor derogation is exquisitely context-sensitive; the types of slurs women use to derogate their rivals vary systematically as a function of mating context (Buss and Schmitt 1993; Schmitt and Buss 1996).

One of the most striking context effects in the domain of mating is the effect of a country's sex ratio – a key dimension of the social environment (Schmitt 2005). Cross-cultural studies of more than 14,000 participants in 48 nations demonstrate that when there is a surplus of women, mating strategies shift toward short-term mating and casual sex. By contrast, when there is a surplus of men, there are observable nation-level shifts toward long-term mating, monogamy, and commitment. This can be understood in economic terms: the mating market is a kind of biological market in which whichever sex is less common is in greater demand and therefore has more bargaining power. Because women, on average, have a stronger desire for long-term mating than men, countries with a dearth of women tend to shift toward long-term mating. By the same logic, because men, on average, have a stronger desire for short-term mating than women, countries with a dearth of men tend to shift toward short-term mating (Schmitt 2005).

These findings highlight that, remarkably, global patterns of casual sex and committed mating can be predicted in advance on the basis of the key contextual cue of sex ratio. Human mating psychology, like the rest of our evolved psychology, is powerfully affected by key contextual cues in ways that can be predicted *a priori* from an evolutionary perspective.

The Breadth and Diversity of Context Effects in Evolutionary Psychology

We have focused on four domains – emotions, altruism, lifespan development, and mating – to illustrate key points about the ecological, social, and internal contexts to which our evolved psychological mechanisms are designed to respond. But even these examples fail to capture the breadth and scope of context effects in evolutionary psychology. In this section, we present a further sampling of context effects to give the reader a sense of how important and ubiquitous context is in evolutionary thinking.

Hunter-gatherer groups differ from one another in their degree of egalitarianism and food sharing. These group differences can be predicted on the basis of resource variability – a key contextual cue (Cashdan 1980). The perceptual bias known as *auditory looming* is heavily context-sensitive, with the bias appearing only for harmonic tones (e.g., sounds created by animate organisms) and disappearing for non-harmonic tones (e.g., background noise such as rain or leaves rustling) – precisely as evolutionary reasoning would predict (Ghazanfar et al. 2002). People tend to be more accepting of women's casual sex, and less moralistic about it, in societies where women are more financially independent (Price et al. 2014). More physically formidable men are more likely to endorse militaristic solutions to national and global problems (Sell et al. 2012) and are more likely to endorse a self-serving position regarding wealth redistribution: among poor men, strength predicts increased support for wealth redistribution, and among rich men, strength predicts increased opposition to wealth redistribution (Petersen et al. 2013). In line with evolutionary reasoning, fathers (but not mothers) show discriminative parental care as a function of facial resemblance between offspring and parent (Platek et al. 2002; Platek et al. 2005). Because parasites degrade physical attractiveness, people attach more importance to physical attractiveness in parts of the world with greater parasite density (Gangestad and Buss 1993). Even women's behavior toward their male kin may be affected

by the context variable of where they are in their fertility cycle (Lieberman et al. 2011).

These findings, across large swaths of content domains in psychology, capture only a fraction of the total set of context-based discoveries in evolutionary psychology. We include them here as a reminder that, despite having chosen to focus on four specific domains, context effects feature prominently in evolutionary psychology and permeate the entire discipline. The misconception that evolved psychological mechanisms are rigid and environmentally insensitive is pervasive, but deeply mistaken (see Al-Shawaf et al. 2018 for a discussion of additional widespread misconceptions about evolution and natural selection).

Conclusion

Our goal has been to demonstrate how essential context and environment are to evolutionary psychology. We think there are three main ways to appreciate this point. First, the environment is crucial to evolved adaptations at every stage of their emergence: their evolution, ontogenetic development, and immediate activation. Evolved adaptations would not exist without the environment, nor would the behaviors they produce. Second, *evolved learning mechanisms* simultaneously illustrate the centrality of context in evolutionary psychology and dissolve the fallacious (but common) dichotomy of “evolved versus learned.” Food aversion learning, hazard-specific fear learning, and incest aversion learning all demonstrate that *learning requires evolved learning mechanisms*, and that these evolved learning mechanisms are highly context-sensitive. Third, a long list of prominent context effects in domains such as emotions, altruism, lifespan development, and mating show that the centrality of context is not just an abstract theoretical point of passing interest, but rather pervades all the empirical work evolutionary psychologists do.

In sum, context is central to the theoretical framework of evolutionary psychology. Without it, evolved psychological mechanisms would not make sense – and would not exist.

Environmental pressures drove the evolution of these mechanisms in the first place, environmental inputs are the keys to activating them in the immediate present, and the primary function of said mechanisms is to extract information from the environment and use this information to adaptively regulate physiology and behavior (Tooby and Cosmides 2015). Looked at in this way, context lies at the heart of modern evolutionary psychology.

Definition

Male-to-male aggression reliably arises in situations where men compete against other men for mates.

Introduction

One robust empirical observation is that men are more aggressive and violent than women. Aggression is behavior intended to hurt another person, and violence is aggressive behavior intended to cause severe physical harm such as death or injury (e.g., Anderson and Bushman 2002). Sex differences in physical aggression and violence are typically in the medium-to-large range (Archer 2009). Moreover, men are the primary perpetrators and victims of violence nearly everywhere in the world. Globally, men comprise 95% of all homicide victims and 80–97% of homicide perpetrators (UN Office on Drugs and Crime 2013). In other mammalian species such as chimpanzees (one of our closest primate relations), males are also the more violent sex.

Although aggressive behavior is often learned, evidence suggests that much male violence is caused by an evolved predisposition. Boys are more aggressive than girls even before 2 years of age, suggesting that men's tendency towards aggression is present before social learning can provide a reasonable explanation for behavior. After 2 years of age, aggression declines in both genders but rises again in 18–30-year-old men but not women. This peak in male violence coincides with men entering the mating market at a time when they have achieved their maximum size and strength (Archer 2009). Sex differences in aggression are also limited to physical aggression and do not include verbal (e.g., insults) or indirect aggression (e.g., gossiping; Archer 2009). These findings imply that physical aggression in ancestral men was adaptive (and may still be in some circumstances). It is these circumstances that elicit male-to-male aggression that this chapter is primarily concerned with.

In Wilson and Daly's (1985) classic article on male-to-male violence, they describe a murder

case from Detroit in which two young men are drinking together with other people. The perpetrator humiliates the victim by lifting him up between his legs. The victim asks to be put down while others laugh at him. The aggression escalates to hitting and eventually the offender shoots and kills the victim. To many observers, this type of violence and escalation of violence seems excessively disproportionate. But what if one of the onlookers was a romantic interest that the victim or both men were trying to impress? What if appearing weak in the peer group might elicit further victimization and loss of status? This chapter first introduces relevant work on men's adaptations for physical aggression. It then examines the contexts in which men are the primary victims and perpetrators of violence. These contexts will show that male-to-male aggression reliably arises in situations where men compete against other men for mates.

Men's Adaptations for Physical Aggression

Evolutionary scientists suggest that men possess adaptive psychological mechanisms and physical abilities that predispose men to fight other men when specific situations are encountered (Archer 2009; Buss and Shackelford 1997; Sell et al. 2012). One fundamental of evolutionary theory is that adaptations must have directly or indirectly solved an adaptive problem and thereby increased reproductive success in past generations. Buss and Shackelford (1997) proposed seven adaptive problems that aggression could solve. Of the seven, five are relevant to male-to-male violence: taking others' resources, defense, inflicting costs on other male sexual rivals, negotiating status hierarchies, and deterring other men from future attack.

To further elaborate on these adaptive problems, men often use violence to forcibly take resources from other men and also defend themselves against other men. This type of raiding and robbery has long been a part of human history and has been observed in chimpanzees. Inflicting costs on sexual rivals occur when men disparage

or weaken other men in front of a potential mate. In extreme cases, men often murder other men who have sex with their sexual partner. Depending on the type of status hierarchy, men who display aggression toward other men are often respected or hold more power than other men. Similarly, aggressiveness or even a reputation for swift and violent retribution can be an effective deterrent to violence from other men. Thus, violence likely solved many adaptive problems faced by ancient men. Such violence probably contributed substantial reproductive benefits to those men who were willing and able to use it effectively.

One putative adaptation that could solve these adaptive problems would be greater physical size and upper body strength (Sell et al. 2012). Upper body strength is important because fighting and using traditional weapons such as spears, clubs, bows, staffs, and swords required upper body strength. Because maintaining upper body strength and larger physical size is metabolically costly, it seems unlikely that these characteristics would have evolved had it not conferred fitness benefits. For men facing these adaptive problems, being larger and stronger than one's opponent would have been helpful in winning physical contests.

At the heart of whether a man behaves violently or not is the cost-benefit analysis. When directed against the right man at the right time, male-to-male violence could increase access to reproductively relevant resources (e.g., money, land) and social status and imbue a reputation for fierceness. These spoils of violence could then be used to attract or coerce women. In the wrong situation, however, enacting violence upon others can be a costly strategy. Psychological mechanisms for weighing the costs and benefits of engaging in violence in certain situations would thus offer men considerable reproductive advantage.

Men do indeed seem to "size up" other men to determine the costs associated with potential aggression. Men possess remarkable abilities to quickly determine the costliness of a potential violent conflict. Many other species also possess these abilities (see Sell et al. 2012). For instance,

people can accurately assess men's upper body strength and fighting ability from their faces, voices, and body (Sell et al. 2012). Moreover, in these studies, both male and female participants were better able to assess male upper body strength than female strength. The ratio of the facial width to height is also particularly important for influencing judgments of aggressiveness and dominance. Thus, the upper body strength and facial features of a male opponent is an important piece of information in the cost-benefit analysis of the decision to use violence or not.

In sum, throughout human evolution, much male-to-male competition has been violent and still is today to a lesser extent. It seems likely that this competition created strong selection pressures which produced physical and psychological adaptations that enhance the likelihood of using violence in certain contexts.

Male-Male Aggression Occurs When There Is Competition for Women

A compelling explanation for the prevalence of male-to-male violence comes from sexual selection theory (Trivers 1972). Sexual selection theory posits that the sex with the greatest minimum investment in producing offspring will be more cautious and choosy in mate selection (Trivers 1972). The maximum number of offspring that women can have is more limited than the number of offspring that men can have. This asymmetry is because women's minimum obligatory parental investment is greater, and women's reproductive success is physiologically limited by the frequency of ovulation and energetic cost of lactation. For these reasons, the cost of indiscriminate mating is greater for women. Thus, women tend to be the "choosier" sex when it comes to selecting a mate. As a result, men often compete against other men to enhance their chances of being chosen as a mate.

Male intrasexual competition is exacerbated by men's high reproductive variance (i.e., the variability in the number of offspring men produce). Men's reproductive variance is greater than that of women, meaning that some men produce many

children and others none. Polygyny, in which one man could monopolize reproductive access to many women, contributes to men's high reproductive variance. Historically, polygyny was common. More than 80% of cultures documented by anthropologists allow for polygyny. Under these conditions, winning mating contests provides the opportunity for reproductive access to a greater number of potentially fertile women and therefore more offspring in the next generation. As a result of this polygynous societal structure, many men will have no reproductive access to women and leave no descendants. Thus, mating competition is a potent selection force for men. High reproductive variability means that men are in competition with other men to accrue mates and reproductively relevant resources.

Aggressive and risk-taking phenotypes appear to increase men's reproductive success when mating competition is intense. Under polygynous mating conditions, men are larger than women and more muscular. In these conditions, men engage in more intrasexual competition and risk-taking behavior. These findings suggest a history in which physical strength, fighting ability, and risk-taking secured men a greater number of mates.

Although counterintuitive, there is good evidence to suggest that risk-taking increases men's reproductive success. In conditions where men have greater reproductive variance, the possibility of greater gains and greater losses increases the likelihood of taking risks to secure a mate. A good example of this proposition comes from an evolutionary simulation by Daly and Wilson (1988). In that computer simulation, each individual possessed low-, medium-, or high-risk competitive reproductive strategies. Competition took the form of fights between two individuals. The simulation showed that selection favored relatively risky competition strategies even when mortality costs were high, providing that the costs of losing and gains of winning were great (i.e., low or high reproductive success). Even though high-risk individuals experienced the greatest mortality, when the gains were associated with high reproductive success, high-risk individuals experienced the greatest fitness.

The finding that high-risk strategies are associated with greater fitness in polygynous mating conditions suggests that males should be most risky and aggressive when they are actively competing for mates. In men, this time period is usually young adulthood, and much evidence documents this heightened aggression. A meta-analysis of 353 studies found that sex differences in physical aggression peaked during the ages of 18–30 years (Archer 2004). Men are most violent when they are in venues where they can compete over women, such as bars and nightclubs. Men's involvement in male-male homicides also peaks during this age range (Daly and Wilson 1988), irrespective of the overall rate in the society.

Further support for the relationship between intrasexual competition and men's aggression comes from data on men's aggression when they are mated and unmated. Men's aggression and risk-proneness decline when they marry and invest in children. This decline is presumably because marriage secures a pathway for men to propagate their genes. However, when men get divorced or their spouse dies, their aggression and risk-taking reverts to levels comparable with single men in their age group. This pattern may result because upon marriage dissolution, men lose reproductive access to their former spouse. The increase in aggression and risk-taking presumably occurs because divorced or widowed men reenter the mating market.

Men's aggression in intrasexually competitive scenarios is selective. In traditional hunter-gatherer societies who are not at war, one of the most common reasons for male-male homicide was competition over a woman. In these instances, murder of a rival often led to securing a mate. This phenomena has been documented in the Tiwi of North Australia, the Inuit of North America, the !Kung of the Kalahari Desert in South Africa, the Siriono of Bolivia, and the Arapesh of New Guinea (Symons 1979). Thus, one effective method of removing a potential rival from the mating pool is homicide. These examples suggest that extreme forms of male-male violence such as homicide can function to increase men's reproductive success in certain contexts.

Male-Male Aggression Occurs When Status Is at Stake

Aggression and violence can also increase reproductive success by elevating male status. High status is ubiquitously preferred by women in potential mates (Buss 1989; Hill and Hurtado 1996). This preference is presumably because status usually confers the ability to provide resources. Resource provision can function as a form of parental investment (Trivers 1972), and men often display their resources to attract and retain mates. In a variety of societies, men who have higher status have greater reproductive success than those who are lower in status (Betzig 1994). High status men tend to obtain and marry women who are sought after and more physically attractive. High status men also have more female mates (Hill and Hurtado 1996). It has been estimated that 8% of modern Asian men have DNA linked to Genghis Khan, which is 0.5% of the male population worldwide. Similar findings have been reported for other “strong men” who ruled in Ireland and China centuries ago.

Successful intrasexual competition – especially when achieved through aggression and violence – is linked to higher social status in men. For example, young men in many tribal societies gained status and honor through homicide (Daly and Wilson 1988). Male warriors in these societies had more children, more sexual partners, and higher status (Chagnon 1988). In the Ache of Paraguay, men who had survived many battles attained status and power as a result of their aggression (Hill and Hurtado 1996). Similar findings are sometimes still observed in current times. In the United States, the most violent gang members are often bestowed the highest status and the most sexual partners (Campbell 1993). These findings suggest that high status confers direct reproductive success to men.

Inherent in these data is the notion that concerns about status drive men's aggression and violence. Indeed, in addition to revenge, competition for status is one of the most widely documented sources of violent conflict. The majority of alcohol-related violent episodes are related to pursuing social status. Experimental

social psychology research shows that men report a greater likelihood of aggressive or costly retaliation against others when their status was threatened (Geniole et al. 2015). Priming status competition in men also increases the likelihood of aggression against other men (Griskevicius et al. 2009). Winning an aggressive bout against a higher status man could yield greater gains by rapidly elevating the aggressor's place in the status hierarchy. For instance, monarchs experienced a much higher rate of homicide than the general population.

A good example of male-to-male aggression caused by status threat is observed in cultures where the rule of law is weak. Nisbett and Cohen (1996) argued that violent retaliation against status threats is adaptive for men in some conditions. When the rule of law is weak, resources such as livestock can be taken by force. In these conditions, cultivating a reputation for aggressive retaliatory ability is paramount as it dissuades potential competitors. Nisbett and Cohen (1996) suggest that a "culture of honor" emerges under these scenarios, in which even trivial slights escalate to violent aggression in an attempt to protect one's reputation. This phenomenon has been confirmed cross-culturally, with revenge and retaliation more prevalent in societies where livestock could be taken by force and where societal institutions are weak. The implication is that under conditions in which a reputation loss may result in resource loss, men are quicker to aggressively defend themselves against status threats.

Much male-male violence results from trivial altercations, which outside observers would declare petty or insignificant. However, threats to status are inherent in many of these altercations (Wilson and Daly 1985). These altercations usually involve one man challenging the status of another. When acquiescing might involve a potential loss of status and respect, neither man stands down. As a result, violence often erupts. In support of this notion, Wilson and Daly (1985) found that the majority of homicides between men concerned real or imagined threats to status. Insults and public humiliation have also been

shown to commonly provoke fights between young men.

The importance of status to men's reproductive success means that situations in which status gains or losses are at stake can elicit male-to-male aggression. Men who fare better in aggressive competitions gain status as a result. In contexts where status threats can result in a loss of resources, men are quick to aggressively defend themselves. The purpose of this aggression and violence is to ensure that their reputation for aggressive retaliation dissuades status challenges.

Male-to-Male Aggression Occurs When Men's Opportunities to Obtain Resources Are Bleak

Another condition that increases men's aggression is when their own social status is low. Women value high status in potential mates (Buss 1989), and when a man has low status (e.g., if he is unemployed or has a low-paying job), his likelihood of marrying drops. Because marriage is one pathway to securing reproductive success, relatively low-status men are at a reproductive disadvantage. Compared to mid- or high-status rivals, low-status men have fewer opportunities to gain status and resources through traditional means. In these circumstances, low-status men can seek out alternative routes for access to status and resources. These alternatives often involve taking more risks to out-compete rivals. For instance, stabbing a drug dealer in the neighborhood and stealing his car and money may help a low-status man garner resources to attract women and a reputation as a formidable opponent. Although this strategy is risky, men who feel they have little to lose might appraise this situation in a way that shifts the balance of the cost-benefit ratio toward violence.

In support of these notions, Wilson and Daly (1985) consistently find that male-to-male homicide perpetrators are more likely to be unemployed and unmarried. Many systematic reviews of the literature on crime and status also link low status with increased crime and homicide in particular. Violence also generally increases amongst

men who lack economic resources or prospects (Daly and Wilson 1988), yet decreases alongside men's opportunities for resource acquisition. As the gross domestic product, college enrollment, and educational opportunities for young adults increase, homicide declines considerably (Hiraiwa-Hasegawa 2005). This relationship is presumably because these factors allow men to focus on gaining status and resources through traditional, non-violent means.

A related scenario that escalates aggression is when income equality – rather than absolute income level – is low. Figueredo et al. (2012) explain that because sexual selection operates on relative reproductive fitness rather than absolute numbers of offspring, even a man with a steady income may feel he is losing out compared to his competitors. Income inequality thus escalates competitive tactics, with those at the bottom of the distribution feeling that they have little to lose from aggressive or risky strategies. In support of this notion, studies consistently demonstrate that the Gini coefficient (in which higher values index greater economic inequality) positively predicts national homicide rates even when controlling for relevant confounding variables (e.g., Walasek and Brown 2015). Income inequality also increases other intrasexual competition behaviors: when the Gini coefficient is high, men and women are more interested in acquiring luxury goods that are used to signal high status to competitors and potential mates (Walasek and Brown 2015).

Aggression and violent crime can ensure low-status men gain reproductively relevant resources that otherwise may not have been available. In this sense, aggression can be used to co-opt the resources of others (Buss and Shackelford 1997). For example, thieves can acquire valuable weapons or money from rivals, mates can be poached from existing relationships, and violence can be used to acquire territory rich with natural resources or other uses. Criminal and violent behavior can also be used to damage a rival's reputation (Buss and Shackelford 1997). By cheating another person out of a resource, the cheater acquires the resource and bestows upon the victim a reputation as someone who is easy to exploit (Buss and Duntley 2008). Such a

reputation could invite future exploitation attempts and diminish the social standing of the victim.

In sum, when men's opportunities to obtain resources are bleak – either because their social status or relative income is low – men are more likely to aggress against other men. In this context, male-to-male aggression can function as an alternative strategy to access status and resources.

Male-to-Male Aggression Occurs When There Is an Abundance of Women

Because men are more aggressive and criminally inclined than women, a seemingly logical conclusion is that when there are more men in a given society, there should be more aggression and crime. As it turns out, this statement is not generally true. Societies with an excess of men usually have lower rates of violent crime (Walsh 2003). Parental investment theory (Trivers 1972) provides one potential explanation for this surprising finding.

Parental investment theory (Trivers 1972) suggests that men's mating strategies are context dependent. In some scenarios, men engage in what is called *direct mating effort*. They compete against other men for access to fertile mates and avoid contributing to parenting. In other scenarios, men focus on *indirect mating effort*: They channel their attention to securing one mate by advertising their ability to parentally invest. Because direct mating effort involves more direct intrasexual competition, it also involves more male-male aggression and violence. By contrast, indirect mating effort often involves garnering economic resources and advertising them to increase the likelihood of securing a long-term partner. Thus, indirect mating competition can shift male intrasexual competition from direct male-to-male aggression to the economic arena.

The operational sex ratio is one environmental feature that influences men's mating strategies and associated aggression and violence. The operational sex ratio in humans is the ratio of sexually active men to fertilizable women. It depends on the reproductive rate of men and women, which is

influenced by the minimum obligatory parental investment and the age at which marriage is likely. When the operational sex ratio is high, there are more men than fertilizable women, making women a scarce resource. In these societies, women's ability to demand greater parental investment and resource potential in men increases. As a result, women are highly sought after as marriage partners, and men often focus on indirect mating effort to attract a wife.

Barber (2009) explains that when women are the scarcer gender, they are less likely to have sex outside of marriage. The implication is that premarital sex would damage a woman's marriage prospects. As a result, there is little direct mating competition between men over sexual access to women, and indirect mating effort is again emphasized. Thus, men in these contexts compete for long-term and marriage partners rather than short-term sex partners (Guttentag and Secord 1983). Because there is less direct mating effort, aggression is reduced.

In contrast, there are also situations where men are the scarce gender. After periods of wartime, for example, the death of many men in combat can result in an excess of fertilizable women compared to sexually active men (a low operational sex ratio). In these situations in which males are a scarce resource, females from a variety of species have been shown to engage in more intrasexual competition (Rosvall 2011). When men are scarcer, women advertise their sexuality, engage in more casual sex, and have more sex outside of marriage (Cashdan 1993). Indeed, there is an inverse relationship between the operational sex ratio and the rate of single parenthood and teen births (Barber 2005). Moreover, after World War II, shortfalls of men significantly increased the rate of out-of-wedlock births in the United States (Guttentag and Secord 1983). The implication is that fewer men make marriage more difficult for women. As a result, women engage in more premarital sexual activity to attract mates because an oversupply of women means that women's marriage prospects are reduced.

The result of this increased propensity towards sexual activity outside of marriage in women is

that direct mating competition increases among men. When fewer barriers exist for sexual access to fertilizable women, men directly compete against other men for mates. The opportunity for reward is high, yet so is the cost of failure (i.e., high and low reproductive success, respectively). Increased direct mating effort means that some men engage in more risky strategies in an attempt to monopolize the mating market and outdo their competitors (Wilson and Daly 1985). Men who were willing to take risks would have had an advantage directly competing for mates and seem to have been more likely to leave descendants (Kruger and Nesse 2004). As a result, male-to-male aggression and violence escalate. Indeed, there is a strong negative association between a society's operational sex ratio and its level of murders, rapes, and assaults (Walsh 2003). This finding has been documented cross-culturally even when controlling for economic development, form of relationships (e.g., polygamy), number of police, population density, drug trafficking, urbanization, infant mortality, and geographical region (Barber 2009).

A secondary mechanism whereby the operational sex ratio may increase violence is through parental investment. When men are the scarce gender and the operational sex ratio is low, marriages tend to be less stable (Guttentag and Secord 1983). There are higher rates of single parenthood and divorce, meaning that paternal investment in offspring is reduced. Again, this finding could reflect increased direct mating effort in men: instead of focusing on parental investment, men focus on directly competing for women. Barber (2009) suggests that research showing that children of single mothers are more criminally inclined is reflective of such conditions in which men are reproductively scarce. These conditions create rearing environments that normalize low-investment reproduction and facilitate antisocial or criminal tendencies in offspring.

Underlying these ideas is the notion that rearing conditions characterized by low paternal investment contribute to what evolutionary scientists call a "fast life history" (Belsky et al. 1991).

Life history theory proposes that an organism's behavior and reproductive strategies are influenced by their physical and ecological environment. When an environment is harsh or unpredictable, a fast life history ensues (Belsky et al. 1991). People with a fast life history have earlier sexual experiences and multiple sex partners, events characteristic of a focus on high offspring numbers and thus direct mating effort. Because the environment is unpredictable, high-risk strategies to attract mates as quickly as possible are more appealing. As a result, crime and aggression increases.

In sum, low operational sex ratios can facilitate violence by enhancing men's direct mating efforts and altering the rearing environment of their subsequent offspring. Offspring raised in these rearing environments are more likely to adopt a fast life history strategy. This fast life history strategy emphasizes direct over indirect mating effort, thus perpetuating the cycle of increased male-to-male violence.

Conclusion

Human evolutionary history has predisposed men to use violence against other men to obtain mates, status, and reproductively relevant resources. This chapter reviewed evidence suggesting that men have evolved physical and psychological adaptations to facilitate male intrasexual competition. Men are physically larger and stronger than women. They very quickly and efficiently use cost-benefit analyses to "size up" potential male opponents from minimal information such as tone of voice or facial features.

An integration of the existing research identified situations that promote violence between men. Because most human societies allow some form of polygyny, men must compete directly or indirectly to appeal to women. Indeed, violence between men peaks when men are part of the dating market and declines after marriage. As in other primate species, status is important for reproductive success. Thus, when men can obtain higher status or experience a threat to their status,

they may use violence to deal with these situations. Poor or otherwise low-status men are most likely to use violence because without status or wealth, men in most countries will have little opportunity to attract a mate. Perhaps the most counterintuitive finding is that a relative abundance of women can facilitate male-to-male violence. In these situations, men can engage in more direct and violent competition for short-term mates rather than in indirect, nonviolent competition.

Even though these situations tend to elicit greater aggression between men, they need not completely determine violent behavior. Human males do indeed have these basic tendencies and adaptations that enhance intrasexual violence in certain contexts and in response to certain types of provocations. However, cultural evolution has produced a substantial decrease in violence over the past few centuries and operates quicker than biological evolution. Thus, hope for reducing male-male aggression will be through the cultural route. For instance, men and boys could be educated about the severe consequences of making seemingly "trivial" status-threatening jokes.

Cultural changes at the institutional levels could also reduce male-male violence. Using sound government economic and social policies to increase wealth may reduce homicide because low-status, poor men tend to be the most common offenders. However, increasing absolute wealth alone may not reduce violence so long as substantial inequality exists in relative wealth. Thus, reducing inequality seems like a valuable means to reduce violence. In sum, although men are predisposed to hurt each other in certain contexts, with awareness and cultural change, they need not be beholden to violent tendencies.

Homicide; Intrasexual competition; Physical aggression; Rape; Rivalry; Sexual coercion; Sexual jealousy; Violence

Definition

Evolutionary pressures on men and women result in sex-specific sexual strategies. Whereas men use physical aggression to secure sexual access and/or to deter rivals, men use sexual aggression to minimize their investment for sexual access and to thwart female sexual choice. Men use distinct forms of aggression against women, because, on average, these behaviors conferred ancestral benefits that exceeded the associated costs.

Introduction

In the context of mating, men and women have engaged in a co-evolutionary arms race. Specifically, reproduction and child-rearing often generate conflict between the sexes. Whereas men more than women pursue a relatively short-term mating strategy, by which they attempt to secure sexual access to multiple partners, women more than men pursue a relatively longer-term mating strategy, by which they attempt to secure resources for themselves and their offspring. One way in which men and women manage conflicting sexual strategies is through physical aggression and violence; an extreme manifestation of which is homicide. However, men commit the majority of instances of intimate partner violence and of

homicide, cross-culturally (Daly and Wilson 1988). Additionally, men use sexual aggression against women to bypass female choice and male-male competition. Similarly to physical violence, men, more often than women, are the perpetrators of sexual coercion and rape (Knight and Sims-Knight 2011).

Sex differences in violence perpetration emerge because of distinctive sexual strategies (Buss and Shackelford 1997). Men and women use aggression differently because of sex-differentiated minimum obligatory parental investment and associated sexual selection (Cross and Campbell 2011). Women, compared to men, invest more time and energy into their offspring, making women a valuable reproductive resource for men. Men, in contrast, invest much less in offspring (e.g., the physiological cost of an ejaculate and the time required to produce it). Because women engage in most of the child-rearing, for ancestral men to have been reproductively successful, they must have outcompeted rivals to secure the attention of high-investing females. Thus, our ancestors include those males who successfully used violence against rival males to gain sexual access to females. However, violence also may have been successfully inflicted on female mates, to thereby assure paternal certainty. More specifically, ancestral men may have used aggression against women and thereby thwarted them from deserting or committing sexual infidelity and are likely to have been more reproductively successful as a consequence (Buss 2014). Whereas it may have been ancestrally adaptive for men to be physically aggressive to combat paternity uncertainty or cuckoldry, female aggression is less likely to have been selected over evolutionary time. Given the investment that women contribute to their offspring, women may have evolved mechanisms, such as greater sensitivity to fear (Cross and Campbell 2011), that motivate them to avoid involvement in physical violence. In fact, research indicates that women engage much less frequently than men in extreme violence (e.g., homicide; Daly and Wilson 1988; Perilla et al. 2011). When women do aggress, this aggression is more likely than men's aggression to be nonlethal.

As with physical aggression, men use sexual aggression against women as a part of a sex-specific sexual strategy (Buss 2014). Sexual aggression (e.g., rape) is one tactic men may use to reduce the investment they trade for female sexual access. By exercising sexual aggression and circumventing female choice, ancestral men may have secured increased reproductive success while contributing fewer resources to the woman who rears their offspring. Thornhill and Palmer (2000) suggest that by sexually coercing women, men may succeed in competition for mates without having to be chosen by a woman or winning male–male competitions for sexual access. In contrast, nonevolutionary explanations of risk factors for sexual coercion or rape suggest that men perpetuate because they have rape-supportive attitudes, perceptual biases (i.e., believing that a woman's friendly behavior is sexual), high alcohol use, and high pornography consumption (especially aggressive genres of porn; Knight and Sims-Knight 2011). However, although it is important to acknowledge these individual characteristics and behaviors of sexually coercive men, those explanations do not engage ultimate causes of sexual aggression.

To avoid cuckoldry and to assure exclusive sexual access to a long-term partner, men's use of *physical* aggression against women is associated with male sexual jealousy, the age of the woman, and sexual rejection. Additionally, men's use of *sexual* aggression against women is associated with the age of the woman, male assessment of the vulnerability of the woman, and various individual differences in men (e.g., disadvantaged men and specialized rapists who are sexually aroused by violent or forceful sex).

Contexts for Men's Physical Aggression Against Women

Although some researchers argue that partner killing by men was not ancestrally adaptive and, therefore, not selected over human evolutionary history (Daly and Wilson 1988), other researchers

argue that men have evolved specialized mechanisms for partner-killing, designed to be deployed when it would have been ancestrally adaptive to do so (i.e., in the context of the threatened departure of a long-term partner; Buss 2006). Specifically, Daly and Wilson (1988) propose that partner-killing is an extreme manifestation of male sexual jealousy or "proprietaryness," unintentionally slipping from control to murder; the killing of a partner would not have provided sufficient reproductive benefits to the killer to outweigh the associated costs. Buss (2006), in contrast, suggests that men have an evolved psychology that motivates killing of a partner when killing produces benefits that exceed the costs. Consistent with both competing hypotheses, homicide and intimate partner violence are inflicted by men to deter partners from sexual infidelity or defecting from the relationship. Physically aggressive and homicidal acts that men commit against their female partners are often triggered by sexual jealousy (i.e., stemming from paternity uncertainty or the threat of cuckoldry), the age of the female partner, and/or experiencing romantic or sexual rejection.

Sexual Jealousy

First, lethal or nonlethal violence is regularly directed by men against their female partners in the context of male sexual jealousy (Buss 2000; Daly and Wilson 1988). In fact, male sexual jealousy is the most common cause of wife battery and a leading cause of uxoricide or wife-killing (Daly and Wilson 1988). Although jealousy is a common experience among both sexes, women report that they would be more distressed by a partner's *emotional* infidelity than *sexual* infidelity; whereas, the opposite pattern is reported by men (Buss et al. 1992). Specifically, men express greater distress by the prospect of or the actual act of a partner's sexual infidelity than by a partner's emotional infidelity. These sex differences in jealousy arise because of differences in evolved sexual strategies that men and women pursue; each

sex has its own set of goals and means of attempting to achieve them. In the conflict of interest between the sexes, women desire to secure long-term relationships in which they can secure resources for themselves and their offspring. However, women may sometimes “out-source” or copulate with other men to obtain higher quality genes for their offspring. If successful, women are assured the resources they need and have secured better genes for their offspring. In the process, they will have successfully deceived their long-term partner into raising and investing in offspring to whom he is not genetically related. Men, on the other hand, and relative to women, have evolved an interest in sex with multiple partners and with lesser investment in any one partner. To assure paternity, however, men may invest in a particular woman for the long-term, in which case they are motivated to thwart her attempts at infidelity. Sexual infidelity by a man's partner can result in the loss of time, effort, and resources in his partner, which could have been spent securing a different mate that would have been sexually faithful. If her sexual infidelity results in cuckoldry, her partner invests precious resources into a rival's offspring. In essence, women have evolved motivation to maintain their sexual autonomy, whereas men coevolved motivation to control their female partner's sexual behavior (Smuts 1992). To control female sexual behavior, male strategies range from physical violence to vigilance. The most extreme form of violence, homicide, occurs most often in the context of male sexual jealousy (Daly and Wilson 1988). In fact, men who kill their partners often do so because of suspected or discovered sexual infidelity, which embodies male concerns with paternity certainty and cuckoldry. Additionally, partner-killing by men most often occurs when the woman attempts to desert her partner and the relationship; in which case, the loss of a reproductively valuable woman to a rival motivates male proprietary aggression (Buss 2014). However, partner-killing by men does not inevitably follow suspected or discovered female partner infidelity or desertion; men

also use nonlethal violence to control their partner's sexual behavior.

Ancestral men recurrently faced the adaptive problem of paternity uncertainty because fertilization occurs within women. Whereas women are never unsure that their offspring are genetically their own, men face the problem of being deceived into providing resources and care for a rival's offspring. Given that men cannot account for their partner's sexual behavior at all times, the possibility of cuckoldry increases as time spent with one's partner decreases (Buss 2000). To combat the threat of cuckoldry, male sexual jealousy may have evolved as a mechanism of detection and as a motivator of subsequent (sometimes violent) action (Buss 2000). Further, male sexual jealousy plays a key role in intimate partner violence (Goetz et al. 2008). Specifically, male physical violence or aggression functions to punish or deter women from sexual infidelity; in these circumstances, violence against women functions as an anticuckoldry tactic. Because women have evolved as the less aggressive sex (due to internal fertilization and the need to protect reproductive and child-rearing capabilities), men can exploit women's interest in self-preservation for their own reproductive gain (i.e., women's fear of physical harm by men may stop them from deserting their partner, increasing their partner's opportunities to reproduce). The sexual jealousy arising from paternity uncertainty also manifests in the most severe form of violence, homicide. For instance, unemployment may influence men's aggression against women in the context of potential cuckoldry. Men who lack sufficient resources may be at a greater risk of cuckoldry than men in higher socioeconomic brackets (Buss 2006). One study found that of the men who killed their partners, 64% were unemployed at the time of the homicide (Easteal 1993). Given women's evolved interest in securing resources and support, it is not surprising that men with fewer expendable resources may be at greater risk of partner infidelity and cuckoldry. Although partner-killing is costly in terms of lost reproductive opportunities and time squandered securing

the murdered partner, the benefits of homicide might sometimes exceed such costs, with the result that selection favored male psychological mechanisms that motivates partner-killing, under particular circumstances (Buss 2006).

Motivated often by sexual jealousy, men attempt to stop women from deserting them through physical violence or killing. Male sexual jealousy is a frequent correlate of such controlling behaviors and violence. Men use both nonlethal (e.g., verbal threats) and more severe (e.g., homicide) forms of violence to control a woman's sexual behavior (Smuts 1992); many of these behaviors can be described as mate retention behaviors. One class of these behaviors is direct mate guarding; while engaging in this form of mate retention, men physically guard a mate and actively dissuade potential mate poachers. Direct mate guarding also includes more explicitly dangerous forms of control such as physical aggression. Men do not exclusively direct their aggression toward other men; violence as a mate retention behavior may include physical aggression against their partner (Shackelford et al. 2005). Specifically, direct mate guarding, monopolization of time, and punishment for a partner's perceived or actual infidelity predict female-directed violence. In sum, violence is closely related to autonomy-preventing mate retention behaviors. By using mate guarding tactics successfully, men inhibit or restrict their partner's sexual opportunities and stop them from deserting, becoming more confident that they are the sire of any offspring produced by their partner (Buss and Shackelford 1997). However, in cases which the woman does abandon her partner, the risk of homicide increases dramatically (Daly and Wilson 1988). Women are most likely to be killed by their estranged partner within the first year after a break-up (Buss 2006). Thus, when nonlethal violence does not prevent female infidelity or relationship defection, men may resort to homicide (Buss 2006). In such cases, a man might benefit from killing his partner, rather than simply letting her go, because she may offer reproductive opportunities to rivals, while he may not be able to replace the mate for his own reproductive endeavors. Further, and in connection with an

earlier point, men who are unemployed kill their partners more often than men who are employed, and these same unemployed men are more inclined to kill or attempt to kill their partner when she breaks off the relationship with them (Eastel 1993). This is because unemployed men typically lack the resources women desire and are less likely to secure a new mate in the future. By eliminating their partner, these men could thereby establish credit for their reputation (in certain cultures) and retain the resources that would have been allocated to the woman.

Age of Woman

The age of a woman predicts the likelihood she will be the target of intimate partner violence or homicide. Young women are more likely to be killed by their partner than are older women (Shackelford et al. 2000). Specifically, women aged 15 to 24 years, within the reproductive age bracket, are most likely to be killed by their partner (Daly and Wilson 1988). Women in the youthful, reproductive periods of their lives are more valuable to men as mates. Younger women are more sexually attractive and desirable to men because youth represents or indicates their fertility, which is important in male mate choice and ancestral male reproductive success. Additionally, males with a youthful and attractive partner gain social status from their mateship to this valuable reproductive commodity. Given the motivation and interest to secure as mates young, fertile women with high reproductive value, male sexual jealousy should be especially sensitive in the context of mateship to younger women. Because younger women are more desirable to male rivals, male sexual jealousy motivates men to defend their partners from mate poachers and sometimes motivates them to use aggression against their partner to stop them from deflecting. Men with younger, reproductive age partners are more likely to commit violence against them to control their sexual behavior (Smuts 1992). Because of the reproductive damage a younger woman (relative to an older woman) can cause her partner as the result of her desertion or sexual infidelity,

nonlethal and lethal violence are much more likely to be deployed by men against younger partners than by men against older partners. Additionally, researchers have investigated whether younger women are killed more often than older women simply because younger women are mated to younger and more violent men. The results of this research found that younger women are more likely to be killed across male partner age groups (Shackelford et al. 2000). In sum, younger women are at greater risk than older women of intimate partner violence and homicide.

Sexual Rejection

Sexual rejection may motivate men's aggression against women. Specifically, nonlethal and nonsexual aggression in response to denial of sexual access is a class of problems that women have faced recurrently over human evolutionary history. One study indicated that male rejection sensitivity is associated to perpetration of intimate partner violence (Downey et al. 2000). In particular, men who indicated a lower threshold for rejection negatively perceive and overreact to their partner's ambiguous or negative behavior, heightening their risk for responding aggressively. These researchers also found that, among college-aged men who indicated they are more invested in their intimate relationships, anxious expectations of rejection predicted their use of violence against their partner. In this context, it is possible that men respond anxiously and aggressively to rejection because they perceive that they have lost the opportunity to mate exclusively with a desired woman. Additionally, other researchers found that experiencing romantic rejection from a sexualized woman increases male aggression (Blake et al. 2017). In this study, when men were romantically rejected by a sexualized woman (sexualized through clothing in a profile picture and in response to sex-related questions) via an online dating platform, the men delivered more severe sound-blasts to the sexually-rejecting woman. Although these studies shed light on nonlethal aggression, sexual or romantic rejection may lead to serious consequences, such as

homicide. Consider desertion or abandonment, for example. Ending a relationship is, in effect, a permanent denial of sexual access and rejection of one's previous partner. When a man's sexual strategy is thwarted, discomfort and anger is expected to rise. Given how costly it is for a man to invest in a woman only to be denied sexual access, male violence may have been ancestrally adaptive in securing future mating attempts or in ending a woman's life to thereby deny rivals sexual access to that woman.

Contexts for Men's Sexual Aggression Against Women

US studies across the nation, criminal justice systems, healthcare systems, and college campuses indicate that men's sexual aggression against women is a widespread and prevalent problem (Knight and Sims-Knight 2011). From an evolutionary perspective, men may use sexual aggression against women to circumvent female choice and thereby to invest fewer resources for sexual access. By avoiding male-male competition for female sexual access and reducing the time, energy, and investment spent courting a desired woman, men may increase their sexual access by use of sexual aggression. Because women have an evolved sexual strategy in which they pursue long-term or committed and high-investing males, men who use sexual aggression against them expose them to undesirable circumstances (i.e., rearing an offspring without receiving resources from a mate). One study suggests that men's sexual aggression against women is extremely upsetting to women (Buss 1989) and much more upsetting than men estimate. Buss (1989) found that among college-aged women, sexual aggression was the single most upsetting act a man could commit out of 147 potentially upsetting actions. Given the conflict of interest between the sexes, a strategy of sexual aggression or rape may have evolved in men, while antirape defenses have co-evolved in women.

Rape refers to the use of force or the threat of force to secure sexual intercourse (penile-vaginal penetration) without a woman's consent (Buss

2014; Thornhill and Palmer 2000). There are two likely evolutionary hypotheses for why men commit rape: rape as a specialized male adaptation (Thornhill and Palmer 2000) and rape as a by-product of other male adaptations (Symons 1979). The human rape-adaptation hypothesis describes a specialized psychological adaptation in which the inclination to sexually aggress against women evolved in male psychology but is only deployed in particular circumstances. For a specialized rape psychology to have been selected, the benefits to ancestral men must have outweighed the associated costs (e.g., although ancestral men may face a physically aggressive husband or partner after committing rape against a woman, they may nevertheless have increased their reproductive success by copulating with an additional woman; McKibbin et al. 2008). In sum, rape may have been ancestrally adaptive when males were able to circumvent female choice and increase their mating opportunities.

In contrast, the by-product hypothesis of rape (Symons 1979) suggests that rape was not selected for but is a by-product of other male evolved psychological mechanisms. In other words, there is no male evolved psychological mechanism specialized to motivate rape because such a mechanism would not have produced net reproductive benefits ancestrally. Symons (1979) suggested that rape is a by-product of adaptations designed to secure sexual access from consenting partners. Specifically, deviations of male psychological mechanisms for desire for sexual variety/novelty, psychological sensitivity to mating opportunities, desire for uncommitted and minimal investment short-term mating, and the general inclination to use physical aggression may inadvertently and as a by-product lead to instances of rape.

The mate deprivation hypothesis of rape, which proposes that men who have little or no sexual access to desirable mates may be more inclined to use sexually coercive tactics, has received inconsistent empirical support (Lalumière et al. 1996). Other researchers suggest that there are several types of rapists (McKibbin et al. 2008), which may shed light on why there

has been inconsistent support of the mate deprivation hypothesis. McKibbin et al. (2008) identify five distinct categories of rapists: disadvantaged men who resort to rape, specialized rapists who are sexually aroused by violent or forceful sex, men who rape opportunistically, high-mating-effort men who exhibit psychopathic tendencies, and partner rapists motivated by actual or suspected risk of sperm competition (e.g., by female sexual infidelity).

It is important to note that although female choice may be thwarted by male sexual aggression, it is possible that women have evolved mechanisms that motivate them to prefer sexually aggressive men. Because men who use sexually coercive behavior may be more reproductively successful over human evolutionary history, women may desire that trait in their own male offspring. For example, one study found that sexually coercive men have consensual sex at an earlier age and have more consensual sex partners than do noncoercive men (Koss and Dinero 1988). This is not to argue that women generally prefer men who rape. In fact, women may also have evolved psychological mechanisms to defend against rape. For instance, Buss (2006) suggests that women's aversion to and intense fear of rape may have been selected because sexual aggression by men has been a recurrent adaptation women have faced over evolutionary history.

Rape Outside of the Context of Intimate Relationships

Rapist Types

First, regarding McKibbin et al. (2008)'s hypothesized rapist types, the fact that disadvantaged men sometimes resort to rape aligns with the description of the mate deprivation hypothesis. This type of rapist includes men who lack or have limited sexual opportunities or cannot access consenting women (Lalumière et al. 1996; Thornhill and Palmer 2000). Disadvantaged men who rape depend on a context-sensitive motivation for rape, engaging in sexual aggression when

deprived of mates by normal means. For example, men in lower socioeconomic status brackets commit a disproportionate number of rapes (Thornhill and Thornhill 1983). In this context, men who lack the resources to secure mates may resort to sexual aggression to achieve mating opportunities. Thornhill and Palmer (2000) suggest that an evolved psychology may motivate instances of rape when men lack resources and/or sexual access to mates.

Second, opportunistic rapists are men who may initially engage consensually with sexually receptive women but resort to sexual aggression when the woman changes her mind or if the possibility of retaliation for rape is low (McKibbin et al. 2008). Opportunistic rapists may be especially inclined to rape when the victim is vulnerable (e.g., during warfare). However, there is little evidence that supports the opportunistic rapist profile directly.

Third, high-mating-effort rapists are hypothesized to be sexually experienced rapists who are aggressive, dominant, have high self-esteem, and psychopathic traits (McKibbin et al. 2008). Unlike disadvantaged men who rape, high-mating-effort rapists do not have difficulty accessing consenting women. Specifically, psychopathic men use high-mating-effort strategies to gain sexual access without much investment, only resorting to sexual aggression when their other tactics do not succeed.

Lastly, McKibbin et al. (2008) discuss “specialized” rapists who report sexual arousal in response to violent or aggressive sexual stimuli. Specialized rapists may have an evolved psychology or arousal pattern in which they experience more rapid ejaculation during rape. Thornhill and Palmer (2000) suggest that a more rapid arousal and ejaculation pattern during rape may have been successful, compared to men who did not exhibit that pattern, because the rapist may avoid retaliation and other possible costs of detection. Additionally, specialized rapists may have evolved psychological adaptations which assess vulnerability of victims, preference for fertile women, and high quantity ejaculates.

Assessment of Vulnerability of Victims

Women who are targets of sexual aggression or rape may be chosen by men because of a psychological mechanism that motivate assessments of the associated risks and benefits of sexual coercion (e.g., “specialized” rapists; Thornhill and Palmer 2000). For example, during warfare, a woman might not have protection from kin or a long-term partner, and a prospective rapist might recognize this and target that woman. In this context, the rape as adaptation hypothesis suggests that men have evolved a vulnerability-detection mechanism specifically designed to assess potential rape victims (Thornhill and Palmer 2000). However, evidence suggesting that men have an evolved psychology that functions specifically to evaluate a woman’s vulnerability to rape is insufficient. In line with the by-product hypothesis of rape, it is possible that men evaluate potential rape victims according to an evolved cost-benefit evaluation mechanism that is not specific to rape (Thornhill and Palmer 2000). In sum, neither the rape-as-adaptation nor rape-as-byproduct hypothesis is uniquely supported by the evidence that women experience sexual aggression or rape in contexts in which they are more vulnerable.

Ejaculate Quality in Rape

Thornhill and Palmer (2000) suggest that there may be an increase in quality of rape ejaculates compared to ejaculates produced during consensual sex. Particularly, an adaptation in men to increase ejaculate quality during rape may be related to sperm competition. An evolved ability to influence ejaculate quality in the context of rape may increase the likelihood of fertilization. If men who rape are able to provide a higher quality ejaculate to the victim, their ejaculate would be better equipped to deal with the higher likelihood of sperm competition. For example, given that attractiveness and youthfulness in women are valuable to men, a highly desirable, young woman may already have a long-term partner whose sperm is already inside her. A rapist may increase their success in sperm competition by

introducing a higher quality ejaculate (e.g., more sperm) into the woman.

Age of the Woman

If rape is an adaptation that increased ancestral male reproductive success, one might expect that rapists would target fertile, reproductive-aged women, as opposed to nonfertile women. Similar to men's use of physical aggression against women, men who rape primarily target young women (Thornhill and Thornhill 1983). Fertility peaks in the mid-20s and women who are raped are disproportionately in that youthful, reproductive age bracket (Thornhill and Palmer 2000). It is possible that a victim-preference mechanism, such as a desire to copulate with younger, more attractive women, may have increased the ancestral reproductive benefits of rape. However, men's preference for reproductive-age women also aligns with the by-product hypothesis of rape given that the preference for young, reproductive-age women is exemplified in both men's choice of consensual partners and rape victims. In sum, the age of the woman is related to rape prevalence but does not address whether rape is motivated by specialized adaptation or as a by-product of other evolved mechanisms.

Rape in the Context of Intimate Relationships

Between 10% and 26% of married women report experiencing rape by their husbands (McKibbin et al. 2008). According to some researchers (Goetz and Shackelford 2006; Thornhill and Palmer 2000), partner rape may be motivated by sperm competition. In the context of suspected or actual sexual infidelity, men may rape their partners in an effort to successfully compete with a rival's sperm. Partner-rape may be an anti-cuckoldry strategy used by men to decrease their paternity uncertainty and risk of cuckoldry. In line with this hypothesis, women are especially at risk of rape by a partner who reports concern about the woman's sexual fidelity during or immediately

following a break-up (Thornhill and Palmer 2000). In this context, faced with potential desertion or abandonment to a rival, men may rape their partner (or ex-partner) to achieve fertilization of a woman who no longer grants them sexual access. Additionally, one study found that men mated to women who have committed sexual infidelity or were suspected to have committed sexual infidelity were more likely to use a variety of sexually aggressive tactics, including physical force and rape (Goetz and Shackelford 2006). Related to the possibility that a man might adjust his ejaculate in a rape context, partnered men also might produce higher quality ejaculates when they rape their partner (compared to ejaculates produced during consensual sex with their partner), in an effort to address perceived greater risk of sperm competition.

Conclusion

Men use distinct methods of physical and sexual aggression for particular reproductive reasons. Men use physical aggression against women to address recurrent adaptive problems of female sexual infidelity, paternity uncertainty, and exclusive sexual access. Although selection may have favored men's use of physical aggression, female aggression may have been mostly unfavorable to women's ancestral reproductive success. Additionally, men use sexual aggression against women to gain sexual access to young, reproductive-age women, to circumvent investment, and to avoid male-male competition. In instances of partner-rape, men use sexual aggression to combat the risk of cuckoldry by engaging in sperm competition. Women rarely use sexual aggression against men. Because women are a valuable reproductive resource that invests heavily in offspring, women do not compete as intensely for sexual access to men. We caution that although men's aggression against women may have been selected over evolutionary time, this does not mean that this aggression is morally good or defensible. It is not. Intimate partner violence, homicide, and rape are global problems

that affect women in devastating ways (e.g., contracting sexually transmitted infections, physical ailments, etc.). Some researchers suggest that further inquiry surrounding domestic violence and physical assault may assist in discovering solutions to combat it (Perilla et al. 2011). Additionally, other researchers suggest that rape prevention programs and policies must gauge proximate and ultimate causes of sexual coercion, as well as incorporate more comprehensive, multilevel strategies that incorporate genetic, social, and behavioral understanding (Knight and Sims-Knight 2011).

Domestic violence; Intimate Partner Violence; Male victims; Violence; Women's Violence

Definition

There is a wealth of literature that demonstrates men's victimisation in intimate relationships, this paper explores explanations of women's aggression towards men. This includes exploring traditional models of intimate partner violence, evolutionary perspectives and critiquing the idea women's violence is only ever in self-defence.

Introduction

Women's violence remains a controversial and yet important topic in recent years for aggression research. For decades, the dominant discourse in the intimate partner violence (IPV) literature has been around historical and cultural social structures that have influenced violence against women. Despite evidence of women's violence in intimate relationships, an exploration of this topic has often been the recipient of accusations such as victim blaming and seen as an attempt to excuse men's violence. The aim of this entry is to explore the literature around women's violence including unpicking current gendered models and looking at the evidence for women's violence towards their partners. A further aim is to explore theoretical explanations for women's violence including evolutionary perspectives, risk factors for women's aggression, and the concept of the abusive personality. The conclusion of this entry will explore the implications for treatment and

intervention for violent women in a sector still rooted in feminist and gendered models of IPV.

Evidence of Women's Violence

Proponents of the gendered model of IPV posit that it is an asymmetrical problem of men's violence towards women and that women's violence does not equate to men's violence in terms of consequences, severity, or frequency. Feminist researchers, such as Dobash and Dobash (1979), believe that the cause of IPV is gender that violence is often used for socially constructed purposes, and by studying it in a different context the root of the problem is missed. For them, the correct interpretation of violence against women is that it forms the extension of the domination and control of wives by their husbands, control that is of historical and social construction. Many feminists acknowledge the statistics that detail women's violence against their partners but argue that these figures represent trivial acts such as a shove or push: they choose to use other statistics, such as police data, to support their argument believing that this adds support to the feminist view that men are much more likely than women to be the perpetrators of IPV.

Early research on IPV, and those examining typologies, only focused on male perpetrators. Within the last 40 years, the research uncovering the extent of women's violence towards their male partners has brought into question the view that the cause is solely to be found in the patriarchal values of society. One of the first researchers to publicize male victims of domestic violence was Suzanne Steinmetz. Her paper in 1978 entitled "The Battered Husband Syndrome" detailed the appearance of men being hit by their wives in comic strips across the world. She further mentions the "charivari," the post-Renaissance custom intended to shame and humiliate men who had "allowed" their wives to abuse them, in public, the target being behavior that was considered a threat to the social order of patriarchy. It involved individuals who violated social norms in the eyes of this patriarchal community and who were disciplined through humiliation and collective rule.

One of the first measures that revealed the frequency of women's violence towards men was the Conflict Tactics Scale (CTS; Straus 1979). It was designed to measure IPV by investigating which of a list of acts they had used in conflict resolution within a set period of time. It is usually used with community and undergraduate samples of married or dating couples and involves respondents completing for their own and their partner's behavior (Archer 1999). Criticisms of the CTS have mainly revolved around the lack of context; some researchers believe that the way the items are listed completely ignores their meaning and the situation in which the act took place. It has been criticized for reducing violence to a "check list of acts" that lack information around motives and consequences. Straus (1990) argued that these criticisms were based on a misunderstanding of the research design behind the use of the measure. He believes that the notion of the CTS ignoring context is based on the assumption that quantitative measures cannot accommodate context. In fact, the CTS does measure this by keeping the context and violence variables separate. The context is further set by asking participants to answer the questionnaire while thinking about a conflict they had had with their partner (or ex-partner). There is divided opinion on the issue of context as some researchers would suggest that violent acts are only those where there is an intent on the part of the perpetrator to cause harm, mainly those meant to injure and cause pain. Archer (1999) found that overall there was underreporting of aggression in both sexes for self-report measures on the CTS compared with victim-reports, and research has demonstrated that women's reports are likely to suffer the same biases that men are. Research has indeed found that women used self-defense as an excuse because they perceived that this was the demand characteristic of the situation, when they were aware this was not an accurate assessment of the incident; the claim of self-defense here was retrospective. The CTS has been used within many countries, but in 2004 Straus published a paper confirming its reliability and validity with high rates of internal consistency and low confounding with social desirability. Other scholars have cited

the creation of the CTS and the series of findings that indicate women are also IPV perpetrators, as two of the ten most important findings within the field of IPV research.

The gender-neutral surveying method of the CTS revealed the extent to which men were hitting women, but also, and more surprisingly, it found evidence that such violence was also bi-directional and female-to-male. Many studies within this field have now demonstrated that women are equally as aggressive to men if not more so. One of the most influential papers was John Archer's (2000) meta-analysis, which examined physical aggression within heterosexual relationships using 82 studies and a total of over 64,000 participants. Archer found that women reported perpetrating aggressive acts towards their partners more frequently than men. Other more recent studies have also found this difference (e.g., Bates et al. 2014), with other research suggesting that bi-directional violence is the most common type experienced in relationships. For example, Próspero and Kim (2009) studied the experience of IPV perpetration and victimization, coercion, and mental health problems, among 676 students. Their findings suggested that the majority of those who experienced IPV were classed as being in mutually violent relationships and that both men and women suffered mental health problems associated with it. Stets and Straus (1989) found that in couples where violence occurred, both partners were violent in around half the cases, then female-only and male-only in about a quarter of the time each. Females were more frequently the perpetrator in unilateral aggression in this and other studies (e.g., Gray and Foshee 1997).

An often-cited criticism of the research exploring and comparing rates of men's and women's IPV is that self-report measures do not capture the circumstances and so it is unlikely that women's violence towards men is particularly impactful. More recently, research has indicated that women's violence has serious physical and psychological consequences for men. For example, Hines et al. (2007) analyzed 190 male callers to the Domestic Abuse Helpline for Men (DAHMH), a national helpline for abuse men in the USA; they

found significant instances of physical aggression with the most common acts including hitting, kicking, and punching. The aggression was severe enough sometimes that the men called the police or sought medical attention. Over 20% reported violence that the authors considered life threatening (e.g., using a weapon such as a knife, or choking), and many men described their female partners targeting their genitals in physical attacks. Research does not currently exist exploring the different acts or patterns that are utilized by men and women within IPV perpetration, but what does exist demonstrates there is significant similarity and overlap.

When considering the impact of IPV on men, previous research has often compared outcomes for male victims compared to female victims; this is not an appropriate comparison as the literature suggests that men and women utilize different coping strategies when dealing with distress and trauma. Men may be more likely to externalize their behavior (e.g., by using alcohol and drugs) and women to internalize theirs, so that it is not a fair comparison (Hines and Malley-Morrison 2001). While there is significantly more research exploring the impact of IPV on women, the research that does exist for men suggests the outcomes are just as severe.

Women's Use of Coercive Control

Coercive control is a form of nonphysical aggression that includes behaviors such as humiliation, threats, degradation, and isolation (e.g., Follingstad and Dehart 2000), which are used to seek power over another in a relationship. Traditional models of IPV have seen control as a central tenant to men's domination of women within relationships; the focus on this patriarchal control has gone onto form the foundation of many perpetrator programs including the Duluth Model (Pence and Paymar 1993). Control is not always thought to be present within violent relationships; Johnson (1995) originally argued that incidents of IPV could be categorized into one of two types of physical aggression. The first he labeled situational couple violence (formerly

common couple violence), which encompasses the kind of violence that occurs when arguments get out of control: he did not believe it to be of any serious consequence and it was unlikely to escalate (Johnson 1995). Intimate terrorism (formerly patriarchal terrorism) involves the use of severe and coercive violence as part of a range of behaviors that men use to dominate and control their female partners. It is this violence found in shelter and prison samples, which is more likely to escalate into something more serious and to have more damaging physical and psychological consequences. His later work expanded the typology from an individual to a dyadic one to encompass all combinations of controlling aggression, noncontrolling aggression, and no aggression (Johnson 2006). Intimate terrorism represents a pattern of controlling aggression with a partner who either is not violent or uses noncontrolling violence. Johnson then added two new patterns of behavior: the first, named "violent resistance," represents violence of a noncontrolling kind in response to controlling aggression from the partner – this often encompasses violence in self-defense but is not confined to this. The other, labeled "mutual violent control," represents a destructive relationship where both partners use controlling aggression. To distinguish between these types of aggression would obviously mean collecting data about self and partner behavior.

Typically, Johnson (1995, 2006) suggested that men would be found within the intimate terrorism category with women being more likely to be in that of violent resistance. While there has been support found for the subtypes of this typology, there has been less support found for the predictors around sex and category membership. For example, Bates et al. (2014) found women were significantly more controlling towards their partners compared to men and that men and women were equally as likely to be categorized in all Johnson's categories. With feminist beliefs around the etiology of control being rooted in patriarchy, it has traditionally been studied just within the context of intimate relationships; the theory being that men's IPV is motivated by something different to when they are aggressive to other men. More recently though, research has

indicated that control is predictive of men's and women's same sex aggression (e.g., Bates et al. 2014) and rather than being a function of patriarchy, it could be more related to a generally aggressive and coercive interpersonal style (e.g., Corvo and deLara 2009).

Women's propensity to control could be seen as being related to their childhood bullying behavior. For boys, bullying is something that involves physical aggression, but for girls it is more indirect, they often use controlling tactics such as humiliation, isolation, and social ostracization to bully other boys and girls and manipulate the social hierarchy. While it was previously thought that the gender difference that existed between boys and girls was that boys showed a preference for physical aggression with girls showing more of a preference for verbal aggression, research has suggested that both boys and girls utilize verbal aggression and the actual differences lay in the use of direct versus indirect means of being aggressive.

Indirect aggression involves inflicting pain in a way that makes it seem as if there was no intention to hurt or harm at all; this leaves the aggressor as less likely to be identified and so consequently, not experience retaliation or punishment. This behavior encompasses acts to influence and often sabotage the social relationships of others, impact on the victims' self-esteem, often through directly expressed rejection, and can include nonverbal behaviors (e.g., facial expressions). Research has suggested that girls actually use more indirect aggression than boys, sometimes attributed to the fact girls' verbal and social skills (essential to utilizing indirectly aggressive tactics) mature earlier than boys (e.g., Bjorkqvist et al. 1992). However, more recent meta-analytic evidence suggests the differences in indirect aggression are actually quite small.

The overlap in behaviors that characterize a pattern of either controlling behavior or indirect aggression is very similar. They are often similar in their impact in terms of isolating the victim, impacting on their self-esteem and well-being and creating longer term issues with relationships and trust. For adult relationships, this can be part of a wider pattern of abuse that occurs, or it can be in

relationships where there is otherwise no violence. With an acknowledgment that both men and women have the proclivity to be psychologically aggressive and controlling, it changes the models of IPV that we have understood and should lead us to question the way IPV treatment and interventions work. It also leads to questions about whether all women's IPV could be considered as self-defensive.

Women's Violence as Self-defensive

Women's violence has also been researched much more since the sexual parity of IPV emerged in the literature. Feminists (e.g., Dobash and Dobash 1979) have suggested that women's violence is only in self-defense or quite trivial, but the literature does not support this. Studies examining IPV in community samples often find that it is mutual. For example, Gray and Foshee (1997) found that 66% of their sample reported being in a mutually violent relationship and that this violence was reciprocal, with participants reporting similar amounts of violence as perpetrators and as victims. When examining sex differences for the couples with only one violent partner, they found a higher proportion of males (26%) reporting being victims of violence only and a higher proportion of females (29%) reporting being perpetrators only. As mentioned above, a common misconception around women's violence is that it does not impact men to the same extent as violence affects women. There are a few studies that provide evidence on this, although the body of literature on the consequences for men is much smaller than that for women. Hines et al. (2007) in their study utilizing the DAMH found that all callers had experienced physical abuse from their female partners, over 90% experienced controlling behavior, and others reported being stalked. Some of the men reported being fearful of their partners' violence. Furthermore, they reported that the men had experienced frustrations with the domestic violence system in terms of seeking help.

O'Leary et al. (1989) examined IPV in a longitudinal study of a community sample and found

that women engaged in all forms of aggressive behavior at a rate equal to, or greater than, that of men. The most common types of aggression were pushing, grabbing, and shoving or slapping, as measured by the CTS. Women also perpetrated IPV in the absence of their partners being violent, which suggests that their aggression was neither exclusively self-defensive nor reciprocal. Studies that have examined which partner hit first have found that not only is the violence mutual in severity but also women more often than men strike the first blow. These studies not only indicate the presence of mutual violence, but also show women's greater perpetration in the absence of their partner's violence. This does not support the belief that their violence is mostly motivated by self-defense. In the UK, the majority of women who kill their partners claim self-defense; only a minority of these have their claim accepted however. Indeed, Christopher Nutall (the Director of the Home Office Research and Statistics Department 1992) stated "more than 90% of those accused of domestic homicide, whether male or female, were indicted for murder. At the trial, 22% of the women but only 5% of the men were acquitted of all charges. The data on the reason for acquittal is incomplete, but it appears that the most successful defence was one of self-defence." So, the majority of men and women who kill their partners appear not to be acting in self-defense. Of those convicted, similar proportions of men and women cite provocation (about a third), slightly more men cite diminished responsibility (around half of men and a third of women) and more women cite "no intent to kill" (a third of women and a fifth of men). These figures are consistent to those cited by authors such as Felson, who suggest police only attributed 10% of husbands killed by their female partners to be in self-defense.

Traditional models of IPV argue that patriarchy allows men to abuse their wives and that society does not reprimand them for doing so because they are upholding the patriarchal values within their home. Felson (2002) is one of the several researchers who have argued that patriarchy is not the norm that is relevant here; instead he suggested that norms of chivalry cause men to

inhibit their aggression towards women. When discussing chivalry, he refers to it as originating in a description of a code of behavior for knights in the middle ages that included protective behavior towards women. Felson argued that it is this norm of chivalry that protects women from men in society – he refers to the inadequacy of the word here also; it implies that this is just to protect women from men, when in fact it includes the protection of women from other men, other women, children, and nonhuman sources such as natural disasters (e.g., women boarding lifeboats first on the Titanic). This is supported by studies that indicate women are more likely to receive help from men with these sex differences often more pronounced when there are audiences present, suggesting that this chivalrous effect is normative.

Chivalry means that there is a greater moral condemnation of violence when the victim is a woman, and more serious punishments for the offenders. Felson believes that chivalry can reflect an exchange of submission, a sort of benevolent sexism (e.g., Glick and Fiske 1996). It is a controversial model as it portrays women as weak and is associated with traditional gender roles; however, Felson argued that there are two sources of evidence that support the chivalrous view that violence against women is viewed negatively. One is the finding that women perpetrate violence in relationships at a rate of that similar to men, and often more frequently (e.g., Archer 2000). Another source is research on reactions to violence against women. Many studies have examined evaluations of IPV and have found men's violence towards women is condemned more negatively than violence towards men (e.g., Sorenson and Taylor 2005). Felson and Feld (2009) analyzed a large representative sample of 810 American adults from a random telephone survey and found that participants were more likely to condemn men's assaults on women than any other gender combinations and they were more likely to report this type of assault to the police. They further found violence against a spouse, especially a female spouse, was condemned more harshly than violence against an acquaintance

of either sex, suggesting that violence is not normative within marriage.

Contrasting Patterns of Sex Differences in Aggression

Many studies have found that women are equally as likely to be physically aggressive towards their partner as men, if not more so (e.g., Archer 2000), including in longitudinal research (e.g., O'Leary et al. 1989). Furthermore, the literature (e.g., Archer 2004) and crime statistics that detail the propensity for men to be more aggressive than women to same-sex others suggests a contrasting pattern of sex differences dependent on the sex and relationship of the opponent. Few studies have studied same-sex aggression and IPV within the same sample, but those that have suggest this same pattern is found. For example, Bates et al. (2014) explored IPV and same-sex aggression in a large sample ($N = 1104$) and found women were significantly more aggressive to their partners, and men were significantly more aggressive to same-sex others.

The different pattern of sex differences found for aggression to same-sex others and to partners raises the question of whether men decrease their violence from same-sex to partner (as emphasized by Felson 2002) or whether women increase their aggression from same-sex to partner. Cross et al. (2011) noted that the usual sex difference (men as more aggressive) is not found within the home and they examined whether men inhibit their aggression to their partner or women increase their aggression, or if both occur. They presented participants with three conflict scenarios and asked them to rate the likelihood of using physical aggression, verbal aggression, explosive acts, and defusing acts against three opponents: a partner, a same-sex friend, and an opposite sex friend. This allowed them to separate out the effects of target sex and relationship, or intimacy. They used effect sizes to express the shift in the behavior from the different opponents. Women were more likely to say that they would use physical and verbal acts of aggression against a partner, and their increase of aggression to a partner appeared to be as a

function of intimacy. They found that when examining the difference in aggression for men, the diminution of their aggression from same-sex to partner was as a direct result of the target sex. This supports Felson's analysis, suggesting that norms of chivalry make men inhibit their aggression towards women. Cross et al. (2011) suggest here women's increase in their aggression to partners could be due to the knowledge that their partners would not hit a woman. This has also been expanded to be examined with self-report, rather than scenario studies with similar findings emerging (e.g., Bates et al. 2014). These findings support Felson's analysis (e.g., Felson 2002), suggesting that norms of chivalry make men inhibit their aggression towards their partner and that women increase theirs due to the lack of social sanctions associated with their aggression. Women are penalized less in both the legal system and judgments of the public.

Many authors have examined evolutionary perspectives on aggression (e.g., Campbell 1999). Sexual selection theory places the origins of the male directional sex difference in human evolutionary history (Archer 2004) with a focus on male competition. As with the majority of mammals, women have the higher parental investment pre- and postbirth, meaning their intrasex competition is less and their ability to be more selective in choosing a mate is greater. Consequently, men have less parental investment but greater male reproductive competition, the more men are able to offer (e.g., in terms of resources) the more attractive they will be to women. This increased competition between men also creates a short-term mating strategy with increased risk in attempting to gain social control over these resources, which would lead to a prediction of men being most violent to men, rather than to women. The magnitude of the sex difference in aggression will then follow that which poses the greater risk, with the greatest difference being for physical aggression and then less so for verbal and indirect aggression. Archer (2009) shows that this magnitude of sex difference in direct physical aggression can be best explained by using sexual selection theory than the alternative social role theory, arguing that male aggression is part of

a sexually selected adaptive set of behaviors. Competition between males is rife and the use of aggression in such competition is likely to make reproductive success more likely.

Campbell (1999) argues that the lower rate of female aggression is an adaptive strategy that is of huge importance in the mother's survival and reproductive success, and is not just an absence of masculine qualities such as risk taking. The greater importance of mothers than fathers to their infants' survival is supported through evidence of gestation periods, lactation, infant dependence, menopause, and the greater likelihood of male desertion. With this in mind, women should be less likely to perpetrate forms of physical aggression as these pose a risk of injury and endangering safety, leading women to weight the cost of physical aggression more highly than men. This in turn would lead to women experiencing higher levels of fear in situations that pose a physical threat, suggesting they may instead utilize a less risky form of aggression, such as indirect aggression, to minimize the possibility of retribution.

Status is less important to women, but they will still compete for resources; in studies with children, however, girls have been shown to prefer verbal behavior and cooperation to competition (the lower risk option). Campbell's (1999) discussion of intrasexual aggression among women indicates that when women resort to this sort of aggression it is to secure resources (e.g., a valuable male) rather than to maintain status within a dominance hierarchy. For example, Campbell et al. (1998) investigated explanations of female-to-female aggression and found support for the hypothesis that it is a function of female poverty in that it results in economic dependence upon men. This is reflected in a positive relationship between assaults and both female unemployment and AFDC receipt (Aid to Families with Dependent Children) with the latter being representative of men's desertion or abandonment of their female partners. Women will be aggressive in order to obtain the necessary resources for their own and their infants' survival.

This evolutionary account of women's propensity to avoid aggression that puts them in physical

danger is then shaped by society, culture, and social norms. For example, as Campbell (1999) suggests, women's aggression is then condemned as abnormal, masculine behavior and due to some sort of pathological disturbance or temporary insanity. She goes further to suggest that feminist researchers would explain this as originating in a patriarchal society that would condemn behavior of this sort by women where as other theories (e.g., Social Role Theory) see it as being related to culture and society when it may in fact be an innate protective mechanism by women. It leaves women with the need to explain and excuse their aggression in a way that men do not.

Campbell (2006) argued that this sex difference in direct aggression is not due to differences in experiences of anger, but due to different experiences of fear. Archer (2004) had already demonstrated there was no sex difference in anger, but other studies have found that women are more likely to experience greater levels of fear and fearfulness of potential danger. Again, fear driving the avoidance of aggression is an adaptive strategy to enhance survival of themselves and therefore their offspring. The sex difference in IPV seems incongruent with this explanation: if women were more fearful, it is unlikely that they would be perpetrating this type of aggression at the same rate as that of men. Their fear of physical injury must be less than for a same-sex or opposite sex stranger opponent, and indeed this is supported by studies suggesting there is a greater perceived danger from strangers than from intimates. A woman's awareness of the social norms that condemn violence against women could work to reduce the fear she may feel in a conflict situation with her partner. This could include the knowledge that if a woman was physically aggressive to her male partner there would be no physical reprisal, and so less, or no physical danger. This knowledge is one developed through knowing their male partners' behavior and values around women, something it is much less likely to know when the man is a stranger or acquaintance.

An alternative theory of the sex differences in aggression comes from Social Role Theory (Eagly 1987), which attributes sex differences in behavior, including aggression, as originating

from early socialization in terms of masculine and feminine sex roles. According to this theory, sex differences in social behavior have arisen historically from the positions and status men and women have held, which creates expectations about characteristics of each sex that are associated with their roles (e.g., women as homemakers, men as providers). Sex roles mean that women's aggression is viewed as incongruent with femininity and so women are more likely to use alternative forms of aggression. These expectations are then transformed into behavior with reinforcement of the differences, leading to different patterns of behavior developing (Eagly 1987). It is clear from developmental studies that boys prefer aggressive acts in play: for example, one study examined the development of preferential play for boys and girls among groups of four-, five-, six-, and nine-year-olds. They found that by 4 years of age, 50% of the boys (but less than 10% of the girls) rated that at least one of their favorite toys was used for inflicting harm through physical aggression on an inanimate object. This effect increased with age and filtered through into TV and media choices.

Archer (2004) performed a meta-analysis examining sex differences in aggression in real-world settings and related his results to both the evolutionary and social role theories. This study found that men were more physically aggressive than women were. The sex difference was smaller for verbal aggression, something that has been found in previous reviews of experimental laboratory studies. Sex differences were absent for anger and mostly absent for indirect aggression, something which is normally found in the female direction in studies of aggression in children. Elements of the results supported both theories, but Archer argued that the overall pattern was more consistent with sexual selection theory in terms of the fact that males were more likely to use risky forms of aggression when they are angry. This raises the question of what females do when they are angry: the most obvious form would be indirect aggression as it carries less risk.

Cross and Campbell (2011) describe the patterns seen in intrasexual aggression and explain that less is seen between women due to their

increased sensitivity to the costs of their aggression and an associated greater fear response. In discussing the contrasting pattern of sex differences, Campbell felt that the cultural norms may influence men's inhibition of their violence towards women, but that these norms would not be enough to reduce women's disinhibition; with an evolutionary mechanism that means women inhibit their aggression through fear of the consequences, it must be something more than this to make women overcome this barrier and allow their aggressive impulses to be enacted towards their male partners. Similarly, women's aggression is only inhibited towards partners, not men in general and yet the cultural and social norms dictate violence against all women is wrong. This fear reduction experienced by women who are violent in intimate relationships, is a fear reduction specific to their partners.

Campbell's work discusses the role of oxytocin in mitigating this issue. Oxytocin is a nonapeptide hormone and a neuromodulator which regulates a number of behaviors around reproduction, and in childbirth and new-born breastfeeding. In animal studies, it has been shown to be important in social behaviors such as partner bonding through sexual activity, and maternal and social bonding. It is also associated with a reduction of fear in animal and human studies; research with humans has shown oxytocin reduces amygdala activity in response to fearful stimuli and other aspects in response to threat.

Oxytocin may reduce inhibition generally, but release of this is context specific and is triggered by their intimacy meaning a partner-specific reduction in fear, so the increase risk of aggression is only directed towards their male partner. Campbell further points to this explanation going some way to understanding why women are aggressive to their male partners even in cultures where there is less gender empowerment for them. Typically, the research on oxytocin focuses on the positive social effects in terms of increased trust, and bonding, but Campbell states "it is a two-sided phenomenon" (p. 396) it increases mother's attachment to her infants but also reduces her fear (and so increases her chance of aggression) in defense of them.

Personality and Psychopathology

Many of the studies of risk factors of aggression and criminality, including those on IPV, have focused very much on male perpetrators. Addressing this issue, Farrington and Painter (2004) examined sex differences in risk factors based on conviction data. They used brothers and sisters in the Delinquency Developmental Investigation which is a longitudinal survey examining the development of offending and antisocial behavior in 411 males first contacted in the 1960s. The criminality rates were much higher for men than for women, with 44% and 12%, respectively, having convictions. There were similarities in predictive risk factors of criminality however: e.g., low family income, large family size, and having convicted parents and siblings (the probability of being convicted increased with the number of other convicted children in the family). However, there were differences, firstly in their choice of crime, with men being convicted more for burglary and theft and women more for shoplifting and crimes of deception. The most predictive risk factors included parental characteristics for men and socioeconomic status and child-rearing factors for women. This study shows that concentrating solely on one sex leaves a gap in understanding and limits the generalizability of the findings. Many of the risk factors that were identified for both sexes here develop early in life, and so this study is important for identifying those at risk and for intervention.

Medeiros and Straus (2006) reported a study of 854 university students and focused on whether risk factors of IPV were similar for men and women. They found that 8 of 21 risk factors were significantly associated with the increased risk of minor acts of IPV perpetration and that all eight were significant for both men and women. These included anger management, dominance, relationship conflict, and substance abuse. For severe acts, 12 risk factors were significantly associated, and nine of these were significant for both men and women – including jealousy, communications problems, and sexual abuse history. The authors suggested that the etiology of IPV is “mostly parallel” for men and women (p. 10) and

the finding that dominance was a risk factor for women as well as men contradicts the assumptions that male dominance alone is at the heart of the cause of IPV.

Ehrensaft et al. (2004) compared clinically abusive relationships (those causing injury, or requiring official intervention, or both), physically aggressive individuals without clinical consequences, and a control group who reported no abusive experiences. There were differences in the associations found, for example, men in these clinically abusive relationships had disinhibitory psychopathology and extensive personality disorders, whereas women had childhood family adversity and aggressive personalities. Similarly, other studies have compared men and women arrested for IPV and found (compared to men) that women were more likely to have higher levels of histrionic, narcissistic, and compulsive traits and were less likely than men to have dependent traits. Other studies have also found differences in risk factors associated with aggression for men and women, whereas some studies have also found similarities. The cross-sectional nature of many studies means firm conclusions about relationships and causality cannot be drawn, but the broad trends suggest that risk factors associated with men's and women's use of aggression are different.

There have not been many studies that have focused solely on women's violence, many focus purely either on men or on comparing men's and women's aggression. Often, with women being less likely to enter the criminal justice system as a partner violent offender, it presents fewer opportunities to work with female offenders. A recent review revealed that within this limited literature, common themes emerged including a high prevalence of trauma related symptoms, emotional dysregulation, substance misuse, attachment issues, and interpersonal dependency. This review also revealed that many perpetrators are also victims of violence, either historically or currently. This points to the complexity of the antecedents to women's violence.

Stressful or traumatic experiences in childhood, often referred to as adverse childhood experiences (ACE), are thought to have a negative and

detrimental impact in adulthood. Indeed, childhood interpersonal trauma has significant and longstanding impact on adult psycho-relational functioning (Dugal et al. 2016). Research has demonstrated the impact of ACE individually, but more recently it is thought that there is a cumulative impact of multiple ACE. Trauma impacts on neurological development that forms the underpinning of how children process and organize their experiences; where there is impaired functioning it forces individuals to find alternatively ways of coping with negative and emotionally provoking experience. ACE have been found to be associated with perpetration and victimization of IPV in adulthood.

Much of the ACE research has explored the impact for men and women using large-scale samples, for example, research indicating that men and women who experience childhood victimization are also at risk for adult violence victimization. Other studies have focused on women specifically; for example, ACE are associated with adolescent pregnancy, and negative outcomes associated with the adolescent pregnancy seem to be more likely related to the ACE than the age of pregnancy. Similarly, women with a higher frequency of ACE in their history were more likely to engage in risky sexual behaviors and more likely to be the victim of IPV.

The literature on risk factors and antecedents to women's aggression is scant in comparison to men's; however, the picture emerging is that men's and women's violence is predicted by a multitude of different factors. To be able to fully understand and intervene with violent women, there needs to be an understanding of what issues contribute to the cause of the violence. The controversy over women's violence and the implications for some gendered models of IPV has stalled the progression of research in this area.

The Abusive Personality: Influence of Attachment and Borderline Personality Traits

Dutton (e.g., 1998) discusses the influence of attachment and personality variables, specifically

traits of borderline personality, in the development of a so-called "Abusive Personality." Borderline personality disorder, or in a less extreme form borderline personality organization, has been discussed within the literature differentially, but there is some agreement around the key characteristics being: an unstable sense of self and issues with identity including experiencing abandonment anxiety, a pattern of intense and unstable interpersonal relationships characterized by issues of dependency, and intense anger and impulsivity which has been found to be tied to substance abuse and sexual promiscuity (e.g., Gunderson 1984). Dutton (e.g., 1998) described borderline personality organization as a continuum of these personality traits and issues that are characterized by issues around identity that manifest in intimate relationships. His work around this pattern of personality traits focused on a sub group of men who were only violent in these intimate relationships, and in which the violence seemed to appear cyclically, mirroring earlier work by other researchers. Here, attachment theory is used as a way of explaining that the interpersonal and relationship functioning of adults is linked to and related to early childhood experiences with caregivers that impact on the models developed of "self" and "other." Intimacy anger develops through a perceived threat of abandonment which is then directed to the person's attachment figure, their romantic partner. Their anger is matched then by their fear of abandonment and a cycle is created where anger is followed by violence and then contrition and dependency. As Dutton (1998) describes is: "These men are literally at their wives' knees or at her throat" (p. 94).

Research has supported this pattern in finding links between insecure attachment, borderline traits, and anger. Indeed, Dutton suggests that these traits are a component of abusiveness that are interacting with earlier learned cues around abuse in intimate relationships (e.g., witnessing IPV between parents). Due to their insecure sense of self and issues with being alone, these men are reliant on their partner to maintain their sense of self, but due to their inability to communicate this effectively to their partner, they appear demanding and often project anger on to their partner

when their needs are not met. After intense anger, there are often periods of contrition and regret which then characterize the cyclical nature of this behavior.

Dutton's work has been significant in understanding men's aggression in relationships, while it has not been explored as widely with violent women, the literature that exists shows promise. Research has previously demonstrated links between attachment anxiety and IPV perpetration as well as with issues such as emotion dysregulation, substance misuse, and interpersonal dependency to women's violence. Research has also demonstrated that women are more likely to possess borderline symptoms compared to men (e.g., Henning et al. 2003). In a study comparing 32 female offenders receiving treatment for their partner violent behavior, to a control group of nonoffending women who were engaged in psychological interventions, Goldenson et al. (2007) found significant differences between the two groups. The partner violent women reported experiencing less attachment security, more trauma symptoms, and more personality psychopathology (e.g., antisocial and borderline traits) compared to the control group. Introduction of trauma symptoms here links this body of literature with that of ACE described above.

Early childhood experiences can be key in influencing the development of later adult behavior including around IPV. Cumulatively, attachment anxiety multiple ACEs, personality and psychopathology are all influential; it is clear how this abusive personality could be mapped on to their violence as an explanatory factor. This personality type is not the only explanatory factor when considering women's aggression, and it indeed points to the development of more typologies of women's behavior that can help us understand the best way to intervene and provide treatment options. Typologies of women's aggression do exist; for example, Graham-Kevan and Archer (2005) investigated three explanations of women's IPV: that it is associated with fear, that it is reciprocal, and that it is coercive in nature. They found that each of the possible explanations received some support. Babcock et al. (2003) attempted to classify

women into Holtzworth-Munroe and Stuart's (1994) typology, using women who had been referred to a treatment agency for abusive behavior. The women were broadly categorized into either "partner only" or "generally violent." Generally violent women were reported to use more instrumental violence, have witnessed their mother's physical aggression, and experienced more traumatic symptoms than those who used IPV only. Babcock et al. posit that the generally violent women have learnt through socialization mechanisms that it is acceptable for women to use violence to resolve conflict.

Are There Sex Differences in Motivations for IPV?

The research discussed demonstrates the prevalence of women's aggression in intimate relationships and clearly highlights the complexity of men's and women's aggression in this context. There have been few studies that directly compare men's and women's motivations to use aggression; however, those that have have found both similarities and differences. For example, Campbell and Muncer (1987) proposed a theory to explain sex differences in aggression in terms of social representations of anger and aggression. They argued that men tend to use aggression in an "instrumental" way, to control other people, whereas women use it in a more "expressive" way, involving a loss of control. From this theory, they developed a measure, the EXPAGG, to assess the extent of instrumental and expressive beliefs about aggression. Studies using this measure have often found the predicted sex difference, in terms of expressive beliefs being higher in women and instrumental beliefs being higher in men. Other research has demonstrated similarities in motives for physical aggression; for example, Elmquist et al. (2014) found that with few exceptions, there were no significant differences between men and women in the motives they endorsed, which included self-defense, expression of negative emotions, communication difficulties, power and control, and jealousy. Other research has also demonstrated both men's and

women's propensity to use violence as a means to control, which could be driven through a fear of abandonment.

Langhinrichsen-Rohling et al. (2012) performed a review to explore motives for men's and women's IPV and noted among other findings that the "heterogeneity in methodology, measurement, and construct development" (p. 457) can make drawing conclusions difficult, which is compounded the fact that motivations are often internalized processes and are not often easy for perpetrators to label. Nevertheless, they found that power and control, self-defense, expression of negative emotions, jealousy, retaliation, and communication difficulties were all common motives, with few gender-specific effects being found. They further suggested motives differ based on the context in which the violence occurs and that more work is needed with more methodologically rigorous studies to fully understand why men and women aggress, as well as the motives to stop aggressing which could inform intervention.

Implications for Treatment and Intervention

Current interventions and treatment options for violent women are limited. Despite evidence of women's violence towards men, there are few women who enter the criminal justice system and are mandated treatment. When they are indeed referred, there are even fewer programs that are suitable for female offenders. Many current interventions still have their roots in the Duluth model of IPV that is about re-educating men about their male privilege and use of patriarchal control. With few options, many women are referred to victim services despite being an admitted aggressor. With so little research exploring the dynamic risk and protective factors associated with women's violence, then it is unlikely we will be able to develop effective, evidence-based perpetrator programs.

As with men's violence, there are complex histories and antecedents to women's aggression, and there is a need for interventions to include a more tailored approach to target individual

needs and comorbid issues (e.g., substance misuse). It would seem there are benefits to women completing programs, research has shown that completing a program as part of a criminal sentence, women showed less aggression towards their partner. The current programs available are not appropriate for women, but then the evidence suggests they are not appropriate for most men either. Rather than purporting the best way forward as being separate programs for men and women, some scholars (e.g., Carney et al. 2007) are highlighting the similarities between partner violent men and women (e.g., personality profiles, trauma, ACE) and that both groups have similar within group heterogeneity. From this, it would seem the design of a program should be tailored to individual need rather than being about gender.

A further issue arises in the way we construct IPV as primarily having a single aggressor and a single victim, rather than seeing the possibility that both people could fit into both groups at different times. Current services have a tendency to focus on "perpetrators" and "victims" separately in their support and intervention; the prevalence of mutual or bidirectional IPV provides a challenge to the way we currently intervene in IPV. As it stands, a bidirectional couple would be likely placed into perpetrator and victim services rather than approaching a couple based therapy, one that could tackle unhealthy conflict resolution strategies and encourage more appropriate means of managing conflict in the relationship.

Conclusion

A wealth of research demonstrates that women's violence in relationships is prevalent, serious, and has physical and psychological impact on male victims. We also understand more about the antecedents and motivations of women's violence than ever before, but with some still significant gaps in knowledge, there is also still a lack of evidence-based practice in the areas of interventions. A consequence of some sectors in society ignoring violence by women includes underfunded male victim support services and few options for women seeking help for their

aggressive behavior. It is also critical to develop methodologically rigorous evaluations to ensure that for both men's and women's programs, there is a commitment to evidence based practice rather than supporting ideological designs.

Evolutionary theory presents a more distal explanation of women's aggression but social theories (e.g., social learning theory, social role theory) also present evidence in understanding both the sex differences in aggression and the motivations behind them. As theories, they are not mutually exclusive and indeed they have been explored together to explore their respective contributions to our understanding of human aggression. For example, the suggestion that our evolutionary history has led men and women to adopt specific roles; these have then developed into social roles which have reinforced these adaptations. In the complexity of something such as human aggression, it can be seen that both approaches are important for understanding the nuances of different types of aggression. For example, IPV has been found to vary across cultures that have more traditional values around gender; cultures that have more gender equality in terms of societal power and gender empowerment see more women's aggression and tend to have the most parity in IPV perpetration (Archer 2006).

The research discussed here highlights that women's violence is sometimes motivated by self-defense, but that this cannot be assumed to be the motivation, more often than not there are other factors that explain more of the variance that exists. A common conclusion in this area is that more research is needed to understand aggression better; this is indeed the case here. There is more we need to understand about women's aggression before we can effectively tackle it as a social issue and, along with men's aggression, work towards reducing it.

Definition

The use of social and indirect aggression by women as a means to compete with other women, mainly in the context of mate search and mate retention.

Introduction

Both men and women face the challenge of deciding how much time, energy, and resources to invest in parenting versus mating efforts, but due to women's higher obligatory (or minimum) parental investments in offspring, men and women also face qualitatively different challenges to their reproductive success (Trivers 1972). These asymmetries in reproductive investments start at conception: for men, one ejaculate during a sexual interaction suffices for males to pass on their genes to the next generation. Should conception be successful, a female in contrast needs to invest in gestation and birth of her offspring and after birth, lactation and childcare. Moreover, it follows that the sex that makes the largest investment in offspring will also incur the highest costs from mating “mistakes,” and as a result will be the most sexually discriminating, focus more on obtaining a long-term mate, and will be the sex in demand. The sex with the lower obligatory

investment is expected to compete more heavily with same-sex members for access to the higher investing sex and to adopt a more opportunistic, short-term mating strategy. However, humans are among the few animal species in which both sexes engage in parental care, with both women *and* men investing heavily in offspring after birth. This high paternal investment causes men to be selective in their mate choice for long-term partners, and since available men are not all of the same mate value, women have to compete with each other for access to – and retention of – the most desirable men (e.g., Campbell 2013).

As will be detailed below, the way women compete with one another is different from the way men compete and will often take the form of indirect or social aggression. The remainder of this chapter will first focus on the types of aggression used by women, before detailing the contexts and contents of women's competition in the context of securing a mate, and the contexts and content of women's competition in the context of retaining a mate.

Types of Aggression

Direct aggression. Direct aggression involves acts to intentionally inflict injury or harm upon another person and it can be physical, verbal, violent, or nonviolent. Direct aggression is not anonymous: the perpetrator can be easily identified, and the target is therefore likely to retaliate, either immediately or at a later time. Therefore, direct aggression – in whichever form – is considered a high-risk activity. Both men and women are more likely to aggress against same-sex individuals, and whereas men are less likely to be aggressive the more intimately they know someone, the reverse is true for women (see Campbell 2013). Sex differences also emerge in victimization of aggression, with men being more likely to be the victim of aggressive acts – perpetrated by men and by women. However, as the risk associated with aggressive behaviors becomes lower, the sex differences tend to disappear. This can be explained by considering the differences in parental investments between men and women and the

qualitatively different adaptive problems they needed to solve during evolutionary history (e.g. Cross and Campbell 2011).

Given their high physical and economic investments, women incur high costs relative to the fitness benefits of engaging in direct aggressive competition with other females: across human societies, it has been shown that children's survival depends almost exclusively on the mother's continued investments. Moreover, a woman's survival benefits not only her own offspring but also her grandchildren. Being harmed during physical competition would negatively affect a mother's ability to provision for herself and her (grand) offspring, and her death would almost certainly have been – and often still is – fatal to her offspring. As a result of these selection pressures, women have evolved to be more risk-averse than men and are less likely to engage in physical or direct intrasexual competition with their rivals. Cross and Campbell (2011) argue that women are thus largely motivated by an avoidance of losses, and that women's lower fear threshold may be a proximate psychological manifestation of this motivation.

Indirect aggression. Indirect – or social – aggression refers to the purposeful, but often covert, manipulation of interpersonal relationships, and includes behaviors such as social exclusion, breaking confidences, spreading rumors, and gossip. Relative to direct (physical) aggression, these acts are less risky since there is a lower likelihood of retaliation or social consequences and are equally or more often employed by women than by men (see also Campbell 2013). The overall goal of the various forms of indirect aggression is usually to exclude rivals from one's social group, while simultaneously damaging their ability to form or maintain a social network of their own. Indirect aggression includes actions such as social exclusion, gossiping, spreading rumors, and defamation of the target. The overall goal of indirect aggression is to reduce a rival's desire, or ability, to engage in competition over mates; this goal may not always be the conscious driving force behind women's indirect aggression, however, but is likely to operate at an unconscious or implicit level. Research shows that indirect

aggression is the preferred way of women to compete with other women, and that it is mainly employed to intimidate rivals, diminish their mate value, or improve one's own mate value. Compared to men, women are more willing to engage in indirect aggression and are better able to pick up on subtle cues to social exclusion (Benenson et al. 2013).

Similar to direct aggression, women's indirect aggression is often targeted at other women, and in particular, at attractive or sexy women. The use of indirect aggressive strategies peaks during adolescence and young adulthood, when fertility is at its highest, and competition over mates is both most relevant and most salient. Research indicates that younger women report significantly more intrasexual competition than women who were past their reproductive peak. For example, in their study on one particular tactic of intrasexual competition, i.e., gossip, (Massar et al. 2012) showed that younger women gossiped more about their romantic rivals than older women did, and that this effect was mediated by younger women's higher mate value. Indeed, gossip as an indirect aggressive tactic is commonly used by women and tends to focus on topics like other women's appearance or sexual conduct. Gossip between females is more negative than gossip between men or mixed-sex pairs, and compared to men, women respond encouragingly and positively to gossip they hear from their female friends. More recently, Davis et al. (in press) established that individuals' intrasexual competitive tendencies predicted the use of gossip as an intrasexual competition strategy. Moreover, these authors report that women are more likely to gossip than men, in particular about physical appearance and social information.

There are also indications that indirect aggression is effective in eliminating the competition, for example, by suppressing a rival's sexual activity: whereas perpetrators of indirect aggression tend to reach sexual maturity at an earlier age, victims of indirect aggression mature later (see White et al. 2010). Moreover, being the victim of indirect peer victimization, including bullying, causes lower self-esteem in girls but not in boys. When discussing women's intersexual and

intrasexual competition in the remainder of this chapter, the implicit assumption will be that these forms of competition utilize indirect aggression, unless specified otherwise.

Competition in the Context of Securing a Mate

Female Intersexual Competition

Choosing the "right" mate is essential to reproductive success. Especially during the early years of life, human children are reliant on their caretakers for survival and require large amounts of care, food, and protection. Although women are capable of rearing children on their own, they may take longer to conceive a next child when they are the only caretaker. Biparental care thus greatly enhances reproductive success. Differences in the minimum obligatory investments in offspring between the sexes also cause a difference in emphasis on which traits are considered desirable – or even necessary – in a mate (Trivers 1972).

Given women's greater obligatory investment in offspring, their reproductive interests are served best if they are able to obtain a long-term mate with the potential and willingness to invest social and material resources in her and their offspring (Buss 1989). Because men with a higher societal status have better access to resources, women have evolved to value social status in long-term mates, as well as the internal attributes that signal the ability to attain high status or a leadership position – such as being a good judge of character, taking initiative, influencing people, and being assertive. Additionally, mates provide protection against (sexual) assaults by other men – i.e., they function as bodyguards – and research has shown that married women are overall less at risk of being victims of sexual assaults than single women (Wilson and Mesnick 1997). Women's fear of crime and feelings of vulnerability for victimization are associated with their preference for physically formidable and aggressive men. For men, the main challenge is finding a fertile mate. However, many of the characteristics which enhance women's mate value, including her

fertility status, are concealed and cannot be directly observed. Men are thus faced with determining a woman's mate value based on external attributes and have evolved to focus on female physical qualities which signal fertility and youth due to their associations with high estrogen levels: full lips, soft hair, smooth skin, colorful cheeks, good muscle tone, and a low waist-to-hip ratio. Indeed, numerous studies have indicated that men place a premium on women's physical attractiveness, both for short-term and long-term relationships (e.g., Buss 1989).

The search to attract the best possible mate causes sometimes fierce intrasexual competition, which is usually focused on the traits preferred by the opposite sex. That is, women compete within the domain of physical attractiveness, whereas men are more likely to compete over social status and resources. Individuals with a high mate value are more likely to achieve a mate with their preferred qualities and have greater reproductive success as a result. Indeed, high-income men report having more frequent sex and more biological children than men with a lower income, and highly attractive women are more likely to be married and have more biological children than less attractive women.

Female Intrasexual Competition

Intrasexual rivalry among females in socially monogamous species, including humans, is a well-documented phenomenon. Group social living substantially increases both male and female fitness, due to, for example, increased access to resources. However, group living also carries costs, such as an increased risk for pathogen infections, and increased competition over access to scarce resources and mates due to the presence of same-sex rivals. Intense intrasexual competition may cause group instability and evolve into intrasexual aggression. Indeed, in many socially living species, rates of female–female aggression increase as the proportion of (fertile) females in the group increases, with pregnant females showing the highest rates of aggression. Indeed, among, for example, wild chacma baboons, sexually receptive females received most aggressive attacks from other females, whereas pregnant

females initiated the most aggression against other females. These processes are likely driven by both mating competition – including suppression of other females' reproduction – as well as competition over access to resources (see Huchard and Cowlshaw 2011). Among humans, intrasexual competition similarly revolves around access to and retention of mates but also concerns status enhancement or avoidance of victimization.

As mentioned above, starting in early childhood, rather than engage in direct aggressive acts, women resort to less costly strategies of competition. In particular, women tend to use relational and indirect forms of aggression – which includes gossip, spreading rumors, and social exclusion (Archer 2004). These forms of aggression in turn may be seen as part of several intrasexual competition *strategies*. In the literature, generally two strategies of intrasexual competition are distinguished, which both men and women employ to compete with rivals: self-promotion and derogation of rivals (e.g., Schmitt and Buss 1996). Self-promotion refers to the enhancement of characteristics, such as physical attractiveness, to increase one's appeal to potential partners, relative to one's rivals, and as such increase one's own chance of winning the competition. Rival derogation on the other hand refers to acts which are intended to decrease one's rivals' appeal and thus decrease their chances of winning the competition (Fisher and Cox 2011). Women in particular are more likely to resort to self-promotion strategies than to competitor derogation (Fisher et al. 2009), but often these strategies are employed simultaneously. As well as advertising their own strong points through the enhancement of their appearance (e.g., by wearing make-up or tight clothes), women attempt to damage their rivals' reputation, mate value, and social standing (Campbell 2013). Fisher and Cox (2011) furthermore state that since there are costs for competing, individuals are likely to resort to strategies which reduce or even eliminate the need for competition. In a series of studies, these authors report that both men and women resort to two additional strategies to compete with others: mate manipulation and competitor manipulation. More specifically, mate manipulation relies on

redirecting a (prospective) mate's attention and activities away from rivals, hiding the latter from the mate, and thereby eliminating the need for competition altogether. Competitor manipulation involves trying to persuade a rival that the mate isn't worth the competition, thereby increasing one's own chances for success with this mate (Fisher and Cox 2011). Fisher and Cox (2011) have shown that after self-promotion, mate manipulation is the strategy most often employed by both men and women. These preferences might exist because of the lower costs of these strategies compared to the other strategies, which are aimed at a rival, but in could severely damage one's own reputation in the eyes of one's mate.

Self-Promotion and Ornamentation

Because men value attractiveness in their romantic partners, women often compete for mates by increasing their own attractiveness and sexiness, relative to the appearance of their competitors (e.g., Buss 1989; Campbell 2013). Women spend considerable time on their appearance, and Western women spend more than twice as much money on appearance-enhancing products – clothing, make-up, jewelry, or cosmetic surgery – than men. Like men, women also consume luxury goods – extravagant trips, jewelry, designer clothes, or expensive cosmetics – to signal their ability and traits to gather and waste such resources. For women, consumption of such luxury goods is however not used to attract mates but rather employed as a strategy to compete with other women. Hudders et al. (2014) showed that women who consume luxury goods were perceived by other women as more formidable rivals, since these women were perceived as more attractive, flirty, young, ambitious, sexy, and less loyal, mature, and smart. Women's desire to appear attractive to prospective mates and to out-compete other women sometimes has consequences which could be detrimental for mental and physical health. For example, Hill and Durante (2011) showed that women who were primed with intersexual courtship and intrasexual competition were more likely to indicate they would be willing to use dangerous diet pills or go sun tanning. Other research has shown that cues to intrasexual

competition cause women to be less satisfied with their bodies and to have lowered self-esteem, as well as to report increased favorability in their attitudes toward restricting their eating, whereas these effects were not found for men.

Several contextual variables influence women's tendency to enhance their attractiveness in response to intersexual and intrasexual competition. One such variable is the mate value of men and women in one's immediate surroundings. Hill and Durante (2011) suggest that women may calibrate their self-promotion efforts in response to the attractiveness of men and women in their social environment. For single women, this means that in order to decide the extent to which they should enhance their appearance, they should take into account both the attractiveness of same-sex competitors, as well as the quality of the potential mates. The presence of very attractive competitors and/or high quality mates in their environment should for single women thus cause increased efforts to engage in self-promotion – even at the expense of (future) health; it is likely however that such efforts at some point reach a “ceiling of effectiveness,” or optimum value. For committed women, these behaviors are more likely to be driven only by mate retention motives and therefore depend on the mate value of same-sex competitors (for similar arguments, see e.g., Fisher and Cox 2011).

Second, recently, researchers (e.g., Linney et al. 2017) have started to focus on *motherhood* as a specific context which both allows and instigates competition among women – termed competitive mothering. Linney et al. (2017) suggest that “Mothers should be prepared to invest energy, time, and resources in their offspring in order to nurture qualities associated with improved future fitness, such as intelligence, popularity, leadership skills, physical coordination, and physical attractiveness. This ‘extra’ investment that goes beyond ensuring mere survival can give a competitive edge to a woman's offspring, ultimately increasing the reproductive success of mother and child relative to their peers” (p. 94). Such maternal competition centers on mothers' assertions of their children's abilities, carrying the implication that they are superior to other mothers.

Competitive mothering shows itself in both specific and nonspecific bragging about one's abilities as a mother, and particularly, about the qualities and academic achievements of one's child, and causes anger, irritation, and annoyance in rival mothers (Linney et al. 2017). However, direct confrontation and hostility are avoided, and the "punishment" of such bragging mothers is more likely to take the form of avoidance, ostracism, or conversational indirect reprimands.

Furthermore, there are indications that the tendency to enhance one's appearance fluctuates throughout a woman's menstrual cycle. Given that the benefits for appearing attractive are highest around the time when conception is most likely, one would expect that women spend more effort to enhance their appearance around ovulation. Indeed, in photographs taken around ovulation, women were judged to want to appear more attractive than in photographs taken during the non-fertile phase (Haselton et al. 2007). Moreover, several studies show that near ovulation, women prefer to wear clothing that is more revealing and sexy and engage in more self-grooming (Durante et al. 2008). Furthermore, women tend to pay more attention to and buy more appearance-enhancing products near ovulation than at other time points during their menstrual cycle. Taken together, these studies thus suggest that particularly around ovulation, women ornament themselves for intrasexual competition.

Competitor Derogation

Although self-promotion is an effective strategy to enhance one's own mate value relative to that of a rival, actively trying to *decrease* a rival's mate value relative to one's own is another common strategy employed by women during intrasexual competition. Competitor derogation can be classified as a form of indirect aggression and takes on various forms, ranging from making quite subtle remarks or taking over conversations involving the rival to very blatantly pointing out a rival's flaws to a male in whom one is interested (Fisher and Cox 2011). There are indications that even though much of women's indirect aggression is covert or subtle, it is nevertheless effective at inflicting harm on rivals, in particular on female

rivals, since women are more likely to pick up on such subtle signals. For example, research has shown that merely receiving an averted eye gaze causes individuals to feel relationally devalued and negatively affects their self-esteem (Wirth et al. 2010). An individual receiving such a subtle social cue is likely to "get the message" and withdraw, particularly if the signal is sent by multiple females. Such subtle cues and indirect methods of aggressing against a rival are thus extremely cost-effective in the sense that it affects a rival's self-evaluations, without much effort on the side of the perpetrator. The main focus of women's competitor derogations is first, a rival's attractiveness and second, her sexual reputation.

Attractiveness. Although men also use competitor derogation, the focus of this derogation differs. Generally, as mentioned above, the intrasexual competitive acts are targeted at those characteristics which are valued in the opposite sex. Female mate value is largely determined by physical attractiveness, and therefore, when attempting to derogate their rivals, women focus mainly on facial attractiveness, weight, or body shape. Fink et al. (2014) report that in a context of intrasexual competition, the physical features men value the most in women are perceived by other women as most threatening: a very feminine face, larger breasts, and a low waist-to-hip ratio. As a way to counter the threat of such attractive rivals, women report often making derogatory comments about the unattractiveness of highly appealing other women. Compared to men, women also report feeling more *schadenfreude* over a same-sex friend's misfortunes, in particular when such events lower their physical attractiveness (e.g., got a bad haircut or developed acne).

Attractive women report being the targets of other women's social aggression more often than unattractive women, and for adolescent girls, being attractive increases the odds of being the victim of verbal derogation up to 35%. Among adolescent boys and girls, bullying is often targeted at body weight, but the specific aggressive strategies differ depending on whether a person is overweight or underweight. For example, Wang, Iannotti, and Luk (2010) showed that whereas overweight boys and girls were often

victims of (verbal) bullying, only the underweight girls were victims of indirect aggression – i.e., gossip and social exclusion. This makes sense in light of the value placed on thinness as a mate value enhancing characteristic for women. Interestingly, in addition to more often being the victim of intrasexual competition, attractive girls and women are also more likely to *use* competitor derogation as an intrasexual competition strategy (Fisher et al. 2009).

Sexual reputation. The second important domain in which women often derogate their rivals is her sexual reputation. Specifically, women's negative remarks about rivals' sexual reputation often center on her being too promiscuous ("a slut") or too chaste ("a tease"). For men, a woman's sexual reputation is important, especially in the context of long-term relationships. Since men who are looking for a long-term mate place a premium on finding a reproductively exclusive mate, accusing competitors of promiscuity and sexual availability may thus be a useful weapon (Campbell 2013). There are indeed indications that women simultaneously derogate a rival's promiscuity while strategically emphasizing their own chastity, for example, by underreporting the number of previous sex partners to a new partner.

A combination of being physically attractive and "easy" looking – i.e. *sexiness* – is then likely to be especially threatening to women, and Vaillancourt and Sharma (2011) showed that this is indeed the case. In their study, women were confronted with either a conservatively dressed or sexily dressed (i.e., wearing tighter and more revealing clothing) confederate. Their verbal and nonverbal responses were videotaped and showed that when the sexy confederate was in the room, women exhibited facial disgust reactions and made derogatory remarks. Moreover, when asked whether they wanted to befriend the confederate or introduce her to their boyfriend, they were more likely to refuse when she was provocatively rather than conservatively dressed. Women thus restrict other women's sexuality by using indirect means of aggression.

Derogation aimed at a rival's sexuality is particularly common in social contexts with a skewed

sex ratio, i.e., where suitable male partners are scarce. In general, women compete for mates by advertising qualities men find attractive, one of which is sexual exclusiveness or fidelity. Moreover, since past behavior is the best predictor for future behavior, challenging other women's sexual reputation is an effective way to influence perceptions of these women's future fidelity. Thus, when the sex ratio is female-biased, women often resort to gossiping and accusing other women of being promiscuous, "easy," or sexually unfaithful, simultaneously damaging a rival's sexual reputation and enhancing one's own. Indeed, experimental research (Arnocky et al. 2014) indicates that mere *perceptions* of mate scarcity – induced by a bogus newspaper article – increased women's intrasexual competitiveness, jealousy, and willingness to aggress indirectly against a same-sex rival. Similarly, women who are led to believe that their environment contains an abundance of rivals are more interested in relative compared to absolute gains in resource allocation tasks, emphasizing that these decisions are driven by a desire to out-compete one's rivals, even at costs to oneself. Finally, in mate-scarce contexts there is a risk that female indirect aggressive behaviors – including rival derogation – escalate into female–female direct (physical) aggression (see also Campbell 2013).

Menstrual cycle effects. Ovulatory shifts in women's use of competitor derogation have also been established. For example, Fisher (2004) showed that compared to nonfertile women, during ovulation, women derogated other women's facial attractiveness more. Moreover, during the ovulatory phase of their cycle, women tend to report increased dehumanization of other women – but not of men or elderly women – e.g., by describing others in animal-related words, and these effects may be driven by estrogen levels in particular (see e.g., Piccoli et al. 2014). In a study with women using hormonal contraceptives, it was shown that as the level of synthetic estrogen in these contraceptives was higher, the women's intrasexual competition also increased, in particular their tendency to objectify other women. Similarly, it has been established that among women using hormonal

contraceptives, higher levels of synthetic estrogen – but not synthetic progesterone – predict increased mate guarding tendencies. As mentioned above, women tend to ornament themselves around ovulation, and this seems especially the case when there is an abundance of rivals in the local environment: when women were told that there were many attractive women in the local environment and subsequently were offered the opportunity to select clothing items from a clothing website, women in the ovulatory phase were much more likely to choose sexy clothing items (Durante et al. 2008). In addition to their own menstrual cycle influencing intrasexual competition, a same-sex *rival's* fertility status might increase women's intrasexual competition and mate retention efforts. For example, Krems et al. (2016) showed that women in a relationship who were exposed to photographs of other women taken during their ovulatory cycle phase reported they would try to avoid or even socially exclude these women, but only when they rated their own partners as highly desirable.

Effectiveness of competition with rivals. Regarding the effectiveness of the intrasexual competitive tactics described above – self-promotion and rival derogation in particular – research has shown that attractive women have a credibility advantage over their less attractive peers. After hearing derogatory remarks about another woman's appearance, men tended to decrease their ratings of the facial attractiveness of this person when the remarks came from an attractive woman (Fisher 2004). Interestingly, Fisher et al. (2010) report that such derogatory comments not only cause men to devalue a woman's attractiveness but also her kindness, trustworthiness, and overall desirability as a mate. Thus, while rival derogation may be an effective strategy to influence perceptions of a rival's attractiveness or sexual permissiveness, it simultaneously decreases the perpetrator's reputation or mate value for men, as well as her appeal as a same-sex ally for women. Moreover, women are aware of the fact that direct, blatant, or unreasonable attacks on another woman's appearance are inappropriate and likely to be counterproductive (Fisher et al. 2010). Thus, although attacking

a rival and her appearance or sexual reputation may be a particularly effective way to reduce her mate value in the eyes of a (prospective) mate, it may backfire in the sense that one's own attractiveness and mate value are reduced as well. These relatively high costs are presumably the reason that women are more likely to resort to self-promotion than to competitor derogation in the context of intrasexual competition (see Fisher and Cox 2011).

Competition in the Context of Retaining a Mate

Female–female competition not only takes place in the context of mate search, but also, and no less intense, in the context of *mate retention*, also referred to as *mate guarding*. Maintenance of the pair bond is, as explained above, essential to a woman's reproductive success and the health and survival of her offspring. Therefore, to protect one's relationship, one needs to fend off potential mate poachers and prevent a mate from defecting. One of the biggest threats to relationship maintenance is a partner's infidelity, and it is threatening for different reasons for men and women. Whereas for men the main adaptive problem of a partner's infidelity is cuckoldry and paternity uncertainty, for women the largest threat is that a partner will divert his resources from her and her offspring to another woman. The threat of infidelity and the resulting emotions – in particular, jealousy – motivate individuals to undertake efforts to retain the partner for the pair bond. Such behaviors which are implicitly or explicitly aimed at maintaining the pair bond are termed mate retention tactics (e.g., Buss and Shackelford 1997). These tactics are often divided into benefit-provisioning tactics and cost-inflicting tactics (see Buss 1988). The former are used to reduce the likelihood of the partner's defection by focusing on enhancing the partner's satisfaction with the relationship and the partner, whereas cost-inflicting strategies focus on reducing a mate's self-perceived mate value, isolating them, and inducing fear of defection.

Variables Influencing Mate Retention Behaviors

Mate retention strategies furthermore can be aimed at the partner (intersexual mate retention tactics) but also at the rival (intrasexual mate retention tactics; Buss 1988). With respect to partner-directed mate retention, like their rival-directed tactics in the context of securing a mate, women's behaviors also follow from parental investment theory (Trivers 1972) and are attuned to the opposite sex' mate preferences. Given men's preference for young, fertile, and attractive women, women's mate retention efforts will be focused on making themselves appear more attractive in an attempt to please their partner – by wearing make-up, jewelry, tight-fitting clothes, or by engaging in weight-loss efforts. These self-promotion tactics simultaneously function to compete with rivals, as described above (e.g., Buss 1988). Another tactic women employ is to intentionally make their partner jealous, e.g., by flirting with another male when he can see it. The type of tactic used is influenced by, among others, cognitions and emotions about one's relationship. For example, committed individuals are more likely to enhance their appearance, whereas individuals in less committed relationships more often report they would intentionally evoke jealousy in their partner. However, in general, as a relationship progresses – and assumedly, commitment increases – the frequency of mate retention seems to decrease. The type of tactic that is used also tends to co-vary with an individual's mate value, such that lower mate-value individuals tend to engage in more cost-inflicting tactics, e.g., controlling behaviors such as isolation of the partner and may even resort to aggression. For example, women tend to engage in subtle indirect verbal aggressive behaviors as a form of mate retention, both towards their partners and their rivals.

Furthermore, women's fecundity – fertility, or the ability to produce offspring – is a predictor of more intense mate guarding: Younger (more fecund) women tend to employ more mate retention strategies (Buss and Shackelford 1997). Moreover, women's mate retention strategies are influenced by their *partner's* mate value. Buss and Shackelford (1997) report that women's mate

retention co-varies with their partner's status striving and income, such that they increased their mate retention activities if they were partnered with a high status male. Menstrual cycle effects have also been reported for the experience of jealousy, such that both partnered and single women report higher levels of jealousy during the fertile phase of their cycle than during non-fertile phases. However, using oral contraceptives caused increased overall levels of jealousy in partnered women, which were similar to the levels reported by fertile (normally cycling) women.

Jealousy and a Rival's Characteristics

Evolutionary psychologists generally agree that jealousy is the emotion that evolved as a response to the adaptive problem of infidelity (Buss and Shackelford 1997). The experience of jealousy thus signals a threat to the relationship and simultaneously motivates the individual to prevent the mate from abandoning the relationship. By definition, jealousy implies the presence of an imagined or actual rival. Overall, a rival who possesses qualities that are believed to be important to the opposite sex or to one's partner tends to evoke more feelings of jealousy than a rival who does not possess those qualities (e.g., Dijkstra and Buunk 1998). Given the sex differences in mate preferences, with physical attractiveness more valued by men, and status- and dominance-related characteristics more valued by women, from an evolutionary psychological perspective, one would expect women to feel more jealous than men when their rival surpasses them on bodily and facial attractiveness, and men to feel more jealous than women when their rival possesses status- and dominance-related characteristics. Research has repeatedly established that these sex differences in rival characteristics that evoke jealousy indeed occur (e.g., Dijkstra and Buunk 1998).

Interestingly, these sex differences in the jealousy-evoking effect of a rival's characteristics are also found in contexts other than mating: for example, in a work context, women tend to report higher levels of jealousy when confronted with physically attractive same-sex individuals than men, and in the context of personnel selection,

women would not hire a physically attractive woman – whereas men would welcome such employees. Interestingly, these results were found for undergraduate students but also for HR professionals. Conversely, not only do women seem to actively hinder attractive women's career advancement, but they also are affected with regard to perceptions of their own professional possibilities. A physically attractive rival in an organizational context caused women to attribute more unfriendliness to her, aroused more jealousy, and negatively affected their expectations for their own career advancement, presumably because women are aware of the fact that attractive individuals are more likely to receive promotions and achieve professional successes (i.e., the “halo” effect; see Buunk et al. 2016).

Massar and Buunk (2011) reasoned that for women, the jealousy-evoking effect of a rival's physical attractiveness is such a fundamental and adaptive process, that such evaluation of rival characteristics may be perceived outside one's conscious awareness. For example, in a study focusing on facial attractiveness, these researchers showed that exposure of mere milliseconds affects women's jealousy, such that they reported higher levels of jealousy after being subliminally exposed to an attractive female than when exposed to an unattractive female. Moreover, similar results were found when participants were primed with body shapes: an hour-glass shaped female figure with a waist-to-hip ratio of 0.7 – considered attractive and “ideal” for women – evoked significantly more jealousy in participants than a figure with an “average” waist-to-hip ratio (of 0.9). Similarly, Maner, Gailliot, Rouby, and Miller (2007) showed that priming individuals with jealousy increased “attentional adhesion” to physically attractive same-sex targets – but not average-looking rivals – particularly for individuals who were dispositionally more worried about intrasexual rivals.

Conclusion

Humans' high bipaternal investments in offspring cause both men and women to be selective in their

mate choice for long-term partners, which in turn causes considerable competition among members of the same sex to gain access to the best quality mates. Since available men are not all of the same mate value, women have to compete with each other for access to – and retention of – the most desirable men (e.g., Campbell 2013). As the current chapter has detailed, women's aggression against other women often takes on the form of indirect and social aggression, particularly, gossiping and social exclusion. Further, given men's preference for young and fertile partners, women's competition takes place mainly in the domain of physical attractiveness. Whether it is in the context of securing a mate or in the context of retaining a mate, competition is likely to take on the form of appearance enhancement or rival derogation. Furthermore, physically attractive rivals are especially threatening to women and evoke more jealousy and mate retention efforts than unattractive (or “average”) rivals, both in a mating as well as professional context. To sum up, the contextual – and hormonal – influences on women's intrasexual competition and aggression signify its dynamic nature.

Definition

The contingent relationship between acts of giving and receiving among social partners.

Introduction

In evolutionary sciences, interest in contingent reciprocity mainly lies in its potential role in the evolution of cooperation and prosociality between genetically unrelated partners (Axelrod and Hamilton 1981; Trivers 1971). Specifically, selection should favor individuals who conditionally cooperate with others as long as future benefits scaled by the likelihood of future interactions outweigh the costs of cooperation (Nowak 2006). Evolutionary models have shown that strategies based on contingent reciprocity, such as tit-for-tat, can be evolutionarily stable (i.e., resistant to invasions of alternative, noncooperative strategies once constituting a significant proportion of a population) in the condition of repeated interactions with same individuals (Axelrod and Hamilton 1981).

These conditions for the evolution of contingent reciprocity can be extended to interactions in a sizable group resembling an n-person prisoner's dilemma (Boyd and Richerson 1988). More recent research also showed that when the degree of contingent reciprocity varies continuously, it is more sustainable than discrete, all-or-none reciprocity in sizable groups, and this sustainability increase with the efficiency of cooperation

(marginal per capita return; Takezawa and Price 2010). Trivers (2010) further identified the following broad conditions affecting the evolution of reciprocal altruism: (1) longevity (affecting the chance of repeated encounters), (2) dispersal rate (affecting the chance of interacting with same organisms), (3) degree of mutual dependence (affecting the benefit of cooperation and the cost of defection), (4) parental care, (5) dominance hierarchy, and (6) agonistic support.

Related Concepts

Contingent reciprocity is sometimes regarded as a synonym of *reciprocal altruism* or *contingent cooperation* (Gurven 2006; Trivers 1971). However, altruism is defined as actions that are beneficial to another organism but “apparently detrimental to the organism performing the action” (Trivers 2010, p. 124). This is not necessarily the case for contingent cooperation or contingent reciprocity in general. For example, humans not only exchange favorable treatment reciprocally, but they also exchange unfavorable treatment reciprocally. This *negative reciprocity* also constitutes contingent reciprocity (Narotzky and Moreno 2002). Nevertheless, most of the research on contingent reciprocity is focused on contingent cooperation and reciprocal altruism.

Reciprocal actions can occur when favors are exchanged over repeated encounters between the same two individuals. Alternatively, reciprocal actions of cooperation can also be contingent upon the reputation of third parties, which is derived from their prosocial actions, even if such actions do not benefit oneself directly. Such models of *indirect reciprocity* (Nowak and Sigmund 2005; See chapters in this book: Indirect Reciprocity; Indirect Reciprocity Theory) and, additionally, models of *generalized reciprocity* show that cooperation can be stable if cooperative individuals tend to associate with each other and if individuals respond cooperatively after they have been assisted by another group member (Barta et al. 2011; Rankin and Taborsky 2009).

Contingent Reciprocity in Other Species

Contingent reciprocity has been invoked to explain cooperation among non-kins in a few nonhuman species. Reciprocated actions in nonhuman animals include joint assaults on predators to save conspecifics by pied flycatcher (Krams et al. 2008), grooming among impala (Hart and Hart 1992), food sharing via blood regurgitation among vampire bats (DeNault and McFarlane 1995; Wilkinson 1988), and grooming, food sharing, and agonistic support in several primate species (De Waal 1997; Brosnan and De Waal 2002). Some of these instances might be explained by alternative mechanisms, including kin selection and mutualism (Clutton-Brock 2009). Nevertheless, contingent reciprocity is not necessarily mutually exclusive with other mechanisms in promoting altruism. Computer simulation based on the case of blood regurgitation among vampire bats, for instance, shows that even after accounting for genetic relatedness, reciprocal altruism might make major contributions to inclusive fitness beyond kin selection in a relatively large social group (Wilkinson 1988).

Experimental evidence for contingent reciprocity is limited even among our closest primate relatives. de Waal (1997) found some evidence that captive chimpanzees trade food for grooming or vice versa in a fashion of direct reciprocity. In an experimental task, Melis et al. (2008) found chimpanzees showed weak reciprocity in helping a familiar group member getting food by unlocking a door. However, chimpanzees failed to show reciprocity in tasks where other-benefiting actions appear effortless or costless (Brosnan et al. 2009; Yamamoto and Tanaka 2009).

The fact that natural instances of reciprocal altruism among genetically unrelated individuals is rare in nonhuman species might be explained by two major constraints. One is the cognitive demands to maintain reciprocity in a large group of individuals (Schino and Aureli 2010). Another constraint is that asymmetries in terms of dominance, resource-gathering abilities, or mate values are so common that the standard prisoner’s dilemma underlying many models of reciprocity

is problematic (Dawkins 2010). Within a dominance hierarchy, the capacity of the dominant individuals to coerce less dominant individuals into cooperation might remove the potential benefits of reciprocity, thus leading to nonreciprocal equilibriums (Dawkins 2010; Trivers 2010). Alternatively, dominance hierarchies might constitute reciprocal relationships if less-dominant individuals exchange their services for dominant individuals' nonaggression or protection. These constraints lead Brosnan and de Waal (2002) to distinguish three different types of reciprocity: (1) *symmetry-based reciprocity*, which is based on symmetrical dyadic relationships (e.g., mutual association, kinship), is the least cognitively complex and present in many nonprimate species, (2) *attitudinal reciprocity*, which relies on mirroring social attitudes of partners, is more cognitively complex and is exhibited by both capuchin monkeys and chimpanzees, and (3) *calculated reciprocity*, which requires mental scorekeeping, is the most cognitively demanding one and found only in humans and some chimpanzees.

The Ontogeny of Contingent Reciprocity in Humans

Compared with nonhuman animals, humans exhibit far more instances of contingent reciprocity. Anthropological studies showed in many small-scale societies, individuals and family units share greater quantities of goods with those that previously shared with them (Gurven 2006). Empirical evidence has also been accumulating regarding the development of the capacity of contingent reciprocity in children.

Early studies provided observational and correlational evidence of children reciprocating help and sharing with those who shared with them earlier. Fujisawa et al. (2008), for example, studied naturally occurring interactions among Japanese children of 3–4 years old and found that children's provision of help and toys to peers correlated with the peers' previous prosocial actions toward them, without explicit instructions. House et al. (2013) paired children aged

3–7.5 years in repeated face-to-face interactions of a Prosocial Game, in which they chose between (1) delivering resources to both oneself and the partner, and (2) delivering resources only to oneself. Results showed that the propensity of contingent reciprocity (in terms of prosocial resource sharing) consistently appear around 5.5 years of age. Finally, the age at which contingent reciprocity emerges seems to also depend on the tasks. Warneke and Tomasello (2013) experimentally manipulated helping and sharing behaviors of social partners before giving 2.5- and 3.5-year-old children the opportunity to help or share with the partner. Whereas previous helping did not influence helping among either group of children, 3.5-year-olds, but not 2.5-year-olds, are more likely to reciprocate previous sharing.

Reasons for the Variability in Contingent Reciprocity in Humans

Different societies differ in the degree or form of contingent reciprocity (Gurven 2006), due to factors such as resource abundance, type of subsistence, and population density. Situational factors that influence the ease of cheat detection, cost/benefit ratio of altruistic actions, and stability of social grouping are likely to differ through time in the same human population. This should cause natural selection to favor developmental plasticity in contingent reciprocity (Trivers 2010).

In some cases, reciprocity can be contingent on the exchange of equivalent services or goods of roughly the same value, whereas in other cases, reciprocal actions are only contingent on efforts (Trivers 2010). Indeed, anthropological evidence supported the claim that exchange imbalances in forager-agriculturalist groups tend to favor lower-producing families. Unequal reciprocity may also be accepted as long as the unequal exchange is better than no exchange (Gurven 2006).

Conclusion

Contingent reciprocity is crucial to understanding the evolution of prosociality among unrelated

organisms. In nonhuman primates and other species, evidence for contingent reciprocity is limited, likely due to the constraints of cognitive demands and/or asymmetrical relationships in dominance hierarchies. In humans, contingent reciprocity appears to emerge around 3–6 years of age, depending on the task involved. Contingent reciprocity might also differ in the form and fullness of the repayment of favors and is likely to show developmental plasticity in humans.

Definition

Preventing pregnancy through the use of a drug, device, or technique.

Introduction

While reproduction is critical for the continuation of a species, excessive reproduction can put strains on resources necessary for the survival of offspring. Availability of food and shelter and the need for support from adults during development are examples of these resources. Mechanisms that limit reproduction have evolved among many species. For example, clutch sizes among certain avian species emerged that resulted in the greatest number of surviving offspring who could subsequently reproduce (Lack 1954). Humans' relatively short history compared to other species and fast societal development have perhaps circumvented natural changes that would limit reproduction. Humans have developed technologies, such as in vitro fertilization, that ameliorate genetic and acquired characteristics that limit reproduction. Humans have also given much effort to preventing neonatal and infant mortality. There have also been great efforts to develop means for limiting reproduction, and these efforts have a long history across many societal structures. Contraceptives, means of preventing pregnancy, vary from behaviors and techniques to drugs and devices, many of which allow for copulatory behaviors to continue while avoiding pregnancy. In this section, the history of contraception and current methods are described.

History

There is a large volume of evidence that attempts to control reproduction throughout human history. The reasoning behind controlling reproduction during early history ranged from mysticism to preventing psychological trauma. Infanticide was a common practice of some preliterate societies to avoid infants born on days considered “unlucky” from bringing bad luck upon the family or village

(Himes 1936). Women of Easter Island often engaged in sexual intercourse with visitors and actively attempted to avoid pregnancy in such instances, possibly because of the temporary nature of the relationship (Himes 1936). The San Carlos Apache of North America would use herbal concoctions when women had multiple stillbirths or other pregnancy losses as a means of reducing the psychological strain on the mother (Hrdlicka 1908). Later in history, religious doctrines strongly influenced the development of contraceptives. The greatly influential Catholic Church forbade attempts at preventing pregnancy other than abstinence and more recently only allows for natural family planning as a contraceptive method, which will be discussed later. Talmudic-Rabbinical law was slightly more lenient, allowing for the use of contraceptives in select circumstances, like if pregnancy would put a woman's health at risk, and only if both the man and woman agreed to use a contraceptive. Islamic laws generally promoted the development of means for avoiding pregnancy. As a result, there are countless examples of contraceptives in ancient Islamic texts (Himes 1936). In modern times, the reasons for using contraceptives have changed from mystical rationalization and purely economic population control toward women's liberty. While there have been some moral objections to contraceptive use, such as the United States' Comstock Law of 1873 that forbade shipment of contraceptives until the 1936 court decision in *United States v. One Package of Japanese Pessaries*, and the Catholic Church continuing to forbid contraceptive use, contraceptives have grown to become more accepted and used across the globe. Along with these societal changes, medical knowledge and technology have rapidly advanced, and contraceptives have become more effective.

Mystical herbal concoctions and incantations aside, early societies perpetuated many somewhat effective methods of contraception. Chief among these was promoting abstinence from sexual intercourse. For example, the Tsonga tribes of Southern Africa forbade men and women from sexual intercourse after a woman delivered a baby until the baby began crawling, even after which sexual intercourse was allowed but not in a manner such

that pregnancy could occur until after the child has been weaned from the mother's breast (Junod 1927). In Madagascar, some tribes held a custom where a man and woman would not cohabit for 3–6 months after the birth of a child (Himes 1936).

Interrupting sexual intercourse prior to male ejaculation, called *coitus interruptus*, was commonly used throughout history and remains a popular method despite lacking efficacy. Many societies had rules and traditions that promoted *coitus interruptus*, including in the island nations in Oceania and many parts of Africa. Another historical means of preventing semen from entering the vagina was *coitus inter femora*, where the male rubs his penis between his partner's thighs. Despite their history and widespread use, these methods were taboo in some Western religions. The Book of Genesis tells a story of Onan, who was obliged to marry his brother's widow and decided their children would be illegitimately proceeded to "spill his seed on the ground" and was subsequently killed by God for this behavior.

Preventing insemination by expelling semen, using spermicidal douches, and blocking the vagina or cervix was also practiced in ancient history. One perhaps effective spermicidal douche of lemon juice in water was observed in tribal Guana and Martinique (Himes 1936). As early as 1800 BCE, the Egyptians wrote about the creation of pastes of honey and acacia leaves that were pressed against the cervix (Dickinson and Bryant 1931). The women of Easter Island similarly used algae and seaweed and in Japan barriers of disks of oiled paper (Himes 1936). Condoms grew in effectiveness and accessibility with the advent of rubber vulcanization in the mid-1800s CE but had existed in some form for hundreds, if not thousands, of years in Japan and Africa.

Early attempts at permanent sterilization were less common. In the Indian archipelago, a manual retroflexion of the uterus was occasionally conducted immediately after an abortion or live delivery in an attempt to prevent any future pregnancies (Himes 1936). This was not particularly effective, but represents one of a few plausible attempts at achieving permanent contraception. Permanent sterilization of males included castration and a process called subincision in parts of

Australia and New Zealand (Himes 1936). Subincision involved bisecting the urethra on the underside of the penis such that urine and semen exited the penis near the testicles instead of at the head of the penis. This redirection of semen may have prevented some pregnancies, but was not necessarily effective.

Many modern contraceptives share fundamental similarities with early methods and have improved as technology and medical knowledge have increased. A substantial advancement in contraceptive technology was the invention of hormonal oral contraceptive pills that became available in the 1960s. Since then, numerous hormonal and non-hormonal contraceptives that share similar mechanisms of action have been developed with increasing effectiveness.

Modern Contraceptives

Techniques

Abstinence The most obvious method for avoiding pregnancy is to abstain from heterosexual vaginal intercourse. Inhibiting behaviors so deeply rooted in evolutionary history is understandably difficult, requiring significant motivation to achieve.

Withdrawal Also known as *coitus interruptus*, it involves removing the penis from the vagina prior to ejaculation. Like abstinence, withdrawal involves inhibiting evolutionarily supported behaviors which can undermine the likelihood of it occurring. As a result, approximately 22% of sexually active women become pregnant in the first year using withdrawal to avoid pregnancy (Trussell 2011).

Fertility Awareness Methods Fertility awareness methods allow sexual intercourse to occur as normal but involve timing sexual intercourse such that it occurs during parts of the female's reproductive cycle when she is unlikely to become pregnant. Examples are the rhythm method and natural family planning. These methods involve monitoring a female's body temperature or cervical mucus characteristics and may also be used to

aid in achieving reproduction by timing sexual intercourse at peak fertility. Inconsistencies in menstrual cycles can undermine these methods and reduce their effectiveness.

Lactational Amenorrhea Method Following childbirth, consistent breastfeeding maintains hormonal levels that suppress ovulation for approximately 6 months. This method is highly effective but is temporary.

Barrier Methods

Condoms Condoms provide a complete barrier between the penis and vagina and as a result are the only contraceptive that can provide protection from both pregnancy and many sexually transmitted infections. The most common condoms are applied to the penis, but female condoms that are inserted into the vagina are also available and are similarly effective. Incorrect application of condoms significantly undermines their effectiveness such that 18–21% of women become pregnant in their first year of use (Trussell 2011). Combining condoms with spermicides, and especially with hormonal contraceptives, provides superior protection from both sexually transmitted infection and pregnancy.

Diaphragm and Sponge Diaphragms and sponges are barriers placed within the vagina that prevent propagation of semen within the vagina. A prescription is needed to obtain a diaphragm in order to ensure an appropriate fit and should be used in conjunction with a spermicidal agent to be effective. Diaphragms with spermicides applied before insertion remain effective for about 6 hours after insertion, and sponges containing spermicides are effective for up to 24 hours after insertion (Hatcher et al. 2011).

Hormonal/Biological Methods

Oral Contraceptive Pills Oral contraceptive pills deliver either progestins or some combination of progestins and estrogens. Administering these hormones systemically prevents pregnancy by inhibiting ovulation and thickening cervical mucus. Regimens may involve “placebo” pills to

allow menses to occur or may involve constant active doses to prevent menses.

Oral contraceptive pills can also be used for emergency contraception. Not to be confused with pills that induce abortions, emergency contraception pills contain high doses of progestins or progestins plus estrogens that disrupt ovulation or thicken cervical mucus to prevent sperm from reaching the egg. Given this mechanism of action, they must be taken within three days of unprotected intercourse to be maximally effective.

Transdermal Patch Systemic administration of combined progestins and estrogens is also available via a transdermal patch. The patch is replaced weekly for 3 weeks, followed by a week without a patch to allow for menses. Like oral contraceptive pills, the hormones delivered by the patch prevent ovulation and thicken cervical mucus.

Intravaginal Ring Intravaginal rings deliver a combination of progestins and estrogens through the mucous membranes of the vagina, which suppresses ovulation and may thicken cervical mucus. A ring is inserted into the vagina and remains for 3 weeks, when it is removed for a week to allow menses to occur.

Injection Injectable formulations of hormones, typically progestins although combined progestins and estrogens have been used in the past, gradually release for up to 3 months per injection. Like other systemic administration of hormones, injectable contraceptives inhibit ovulation and thicken cervical mucus. Unlike pills, patches, and rings, injections are administered by a medical provider instead of the individual.

Implant Subdermal implants are placed in the arm and slowly release progestins for up to 3 years. The steady release of progestins suppresses ovulation and thickens cervical mucus providing constant and highly effective contraception with minimal effort. A provider with specialized training is required to administer and remove the implant.

Intrauterine Devices Intrauterine devices (IUDs) are inserted into the uterus by a trained

provider and provide consistent, highly effective contraception for up to 12 years. Hormonal IUDs release progestins directly into the uterus, which thickens the cervical mucus and causes the endometrium to release substances that inhibit fertilization. Suppression of ovulation is not as consistent as with systemically administered hormonal contraceptives. Hormonal IUDs provide protection for up to 5 years. Copper IUDs increase levels of white blood cells, enzymes, and copper ions in the uterus and fallopian tubes, all of which prevent spermatozoa from surviving to fertilize an egg. Copper IUDs can provide protection for up to 12 years.

Permanent Methods

Female Sterilization Surgically obstructing the fallopian tubes is the most common method of permanently preventing future pregnancies. This minor surgical procedure can be conducted on an outpatient basis or immediately following an abortion or delivery. Pregnancy following such sterilization is extremely rare.

Vasectomy Physically separating the vas deferens, the vessel that carries sperm to the ejaculate, provides permanent sterilization to men. Impregnation of a female is extremely rare following vasectomy.

Conclusion

Contraception has developed over the course of human history, with modern medical and technological enhancements resulting in a multitude of highly effective drugs, devices, and techniques. Globally, acceptance of contraception has generally increased, fostered, and inhibited by cultural factors. One common thread throughout the history of contraception is that it has been predominantly focused on affecting females. Of a handful of potential candidates, no systemic contraceptive for males has been developed to the point of clinical use. This may be the next frontier for the continuing development of contraceptives.

Definitions

Issues that provoke differing opinions in the study of animal behavior and cognition.

Introduction

Comparative psychology, perhaps more than any other domain of psychology, is fraught with controversy, most clearly in the realm of comparative cognition. Controversy centers around the fundamental question of whether Darwin was correct to postulate continuity in cognitive processes across species, including humans (Darwin 1871), or whether skeptics, known as “scoffers,” are justified in discounting the degree of continuity between man and other animals (Penn et al. 2008). Researchers sympathetic to the notion of continuity focus on results from studies investigating such topics as self-awareness, metacognition, episodic memory, imitation and culture, prosocial sentiments, causal reasoning, tool use, language, and, most notably, theory of mind (ToM). Over the last several decades, these researchers, known as “boosters,” have amassed a significant amount of data that purports to support the notion that animals share at least some elements of abilities previously thought unique to humans. However, a careful and critical read of such studies indicates that, even if animals share some components of traits such as ToM, the way in which these traits are expressed is fundamentally different from the manner in which the same traits are expressed in humans. Researchers, however, have been reluctant to accept such differences, often failing to appreciate that studying evolution is as much about acknowledging differences as it is about finding similarities (Vonk and Povinelli 2006). Thus, controversies exist because the same data is often viewed as supporting two completely different propositions depending on the bias of the researcher. Specific controversies are summarized in the following areas.

Self-Awareness

In the centuries following the famously misquoted Descartes declaration of “I think therefore I am,” (Descartes 1637), philosophers and psychologists alike have probed the question of whether any other species share the human tendency to reflect on their own existence. Gallup (1970) developed the mirror self-recognition (MSR) mark test for use with human children and nonhuman primates. Studies showed that human children investigate an otherwise inaccessible area of their face when in front of a mirror, indicating a recognition that the mirror image depicts themselves, at around the same age that they start using personal pronouns, further lending credibility to the notion that the test assesses self-awareness (Amsterdam 1972). The task, where behavior in front of a mirror is observed before and after an animal’s appearance is surreptitiously altered, typically with a small amount of paint on their face, has now been used with a variety of animals ranging from ants, birds, dolphins, elephants, and various primate species, with most researchers converging on the notion that MSR is shown by great apes but not by other primates. Research on non-primates is more controversial, as evidence for traits thought to be unique to humans found in species more distantly related to humans is often highly scrutinized. Even if one accepts evidence of MSR in non-humans, researchers have debated the extent to which the task measures self-awareness. For instance, some have suggested that successful investigation of the mark during the mirror test indicates mere body self-awareness, but not a true concept of self (Swartz 1997). In this light, the ability to pass the mark test cannot address whether an animal is self-conscious, nor can it determine whether species that are capable of MSR have self-conceptions identical or even similar to those in humans (Swartz 1997). Success on the mark test may simply indicate an animal’s ability to utilize its mirror image to differentiate itself from other features in the environment (De Veer and Van Den Bos 1999).

Metacognition

Similar to the studies on self-recognition, studies of metacognition – the ability to think about thoughts, including one’s own – aim to assess the extent to which other animals are self-aware. Studies of metacognition focus primarily on meta-memory – the animal’s awareness of the strength of its own memory and strategies that could be used to enhance performance in memory tests. Despite significant progress by comparative psychologists, arguments ensue over whether strategies used by nonhumans in experimental tests reflect true meta-memory versus associative strategies (Smith et al. 2006, 2009). To rebut such claims, researchers have devised ever more elegant paradigms to tap into nonhuman memory strategies.

One class of metacognitive tasks involves the use of uncertainty monitoring whereby animals can indicate whether they are uncertain of their own memory and can opt for an “uncertain” response, rather than being penalized for an incorrect judgment. Animals tend to use the uncertainty response judiciously and efficiently, opting out of trials for which memory would be weaker, such as at longer retention intervals, and when perceptual discriminations are more difficult. Researchers utilizing the uncertainty response paradigm suggest that an animal’s metacognitive capacities can be revealed by their adaptive use of the uncertain response option in difficult trials or when they lack sufficient information. However, skeptics have debated the extent to which such strategies are consciously controlled (Carruthers 2008). In the hotly debated area of animal metacognition, researchers should be wary of attributing animal behavior to sophisticated skills such as metacognition until low-level associate mechanisms can be ruled out (Smith et al. 2009).

Given controversies with the uncertainty response paradigms, researchers have more recently focused on information-seeking strategy tasks (Call 2012). In these types of tests, animals should be expected to seek information only when they know (or remember) that they have not been

provided with the relevant information with which to solve the task. As with other aspects of cognition, the data reveal strategies similar to those used by humans but not the full suite of capacities demonstrated by humans.

Episodic-Like Memory

Related to the issue of meta-memory and self-awareness, human memory was thought to be unique in that it involved auto-noetic consciousness (Tulving 2005). This auto-noetic or mental time travel component allows individuals to relive the subjective experience, as well as to recall the objective facts of a previous event. Comparative researchers have operationalized such memory as involving the binding of information about what, when, and where components of an event (i.e., the WWW memory phenomena). They have considered memory that integrates WWW information to be “episodic-like” because it is impossible to access the subjective experience of animals in the same way that one can query humans about the content of their memories. As is often the case in comparative psychology, the cognitive processes of nonhuman animals are deemed less sophisticated than those in humans, solely because researchers lack the means to irrefutably tap into an animal’s subjective experience. Work by Clayton and others has famously demonstrated that animals, such as scrub jays, can remember what type of food was buried in what location when. For example, jays search where they hid preferred wax worms at short delays but retrieve less preferred peanuts at longer delays, only if they have experience with the decay of worms (Clayton and Dickinson 1998). Whereas most psychologists accept the findings as indicative of episodic-like memory, they debate the extent to which such memories are reflected upon in the manner that humans might do when writing an autobiographical retrospective. Rather, animals may use information about past events simply to predict future occurrences. Researchers argue about whether it is possible to ever know the

content of a nonhuman's memories. In addition, researchers have debated whether animals show strong evidence of planning for the future.

Imitation and Culture

As with most of the topics that are hotly contested in comparative psychology today, early anthropologists and psychologists had an anthropocentric view of culture. This notion has been slowly changing in the last 70 years, since the concept of nonhuman animals having cultures was first proposed in 1952 by the Japanese primatologist, Kinji Imanishi, who posited that culture should exist in all group-living species (Huffman et al. 2008). Much of the debate surrounding nonhuman animal culture or behavioral tradition involves definitional disagreements for what truly constitutes culture. Essential to identifying culture is the presence of learning and social transmission of knowledge and skills among animals, leading to behavioral variation within and across species that cannot be accounted for by asocial learning, ecological, or genetic factors. Some animal behaviorists consider any socially transmitted modifications of behavior to exhibit cultural tradition, regardless of the underlying processes (Kummer 1971). However, other researchers such as Goodall and Galef emphasize that determining the presence of culture necessarily depends on how the information is transmitted, which in human populations is primarily through teaching or learning by imitation (Galef 1992). Many notable cases of purported animal culture can be explained by simpler mechanisms of transmission than pedagogy and imitation, two extremely contentious topics within comparative research. For instance, the famous case of various bird species in England learning to open milk bottles in the 1940s can be explained via stimulus enhancement, whereby another animal's attention was inadvertently drawn to the milk bottles by the action of one bird opening the bottle, ultimately leading to the observer learning to open the bottle faster (Galef 1992).

Whereas cultures within human populations typically expand and become more complex and efficient over generations, most supposed forms

of nonhuman animal cultures encompass behaviors that each animal could have learned independently (Galef 1992). Other well-known cases of purported animal culture are the propagation of washing sand off of sweet potatoes in streams by Japanese macaques and termite "fishing" by chimpanzees in Gombe National Park (Goodall 1971; Kawamura 1959). It has been argued that the extremely slow acquisition rate of the potato-washing behavior for other macaques (roughly 2 years after the first macaque began washing) is inconsistent with imitative learning, which is typically relatively quick, as trial-and-error learning is not needed (Galef 1992). Further, the method of fishing for termites was unable to be replicated. Despite the contention over whether imitative learning or teaching result in various behavioral traditions in animal groups, examples of non-imitative variations in behavior that resemble culture are found in rats, dolphins, fish, birds, and primates.

Prosocial Sentiments

Humans may be truly unique with regard to the extent to which they will assist others at some cost and no benefit to themselves. This question was poorly investigated until the groundbreaking work of Silk and colleagues (Silk et al. 2005), which incited hundreds of further comparative investigations. This seminal experiment found no evidence for other regarding preferences in chimpanzees, as the chimpanzees did not take advantage of a reward option where both the actor and the recipient chimpanzee would receive identical food rewards more frequently than the option where only the actor received an equivalent reward. Despite the explosion of empirical work on this topic, researchers have failed to come to a consensus as to whether other species also show prosocial motivations. Although they are often observed to assist others, such behavior can generally be attributed to kin selection, reciprocity, or mutualism. Even chimpanzees are unlikely to provide food to conspecifics even at no cost to themselves although they can be observed to help humans in helping contexts (Warneken and Tomasello 2006). Researchers have shown that

even rodents will release a trapped conspecific and even share a highly desired food with that rescued groupmate, (Ben-Ami Bartal et al. 2014); however, others have suggested that the rats were motivated by a desire to reduce their own distress rather than a truly prosocial concern for others.

Causal Reasoning and Tool Use

Tool use was also once deemed unique to humans. However, that notion has been dispelled, notably by Jane Goodall in 1960, when she observed a chimpanzee using a piece of grass to acquire termites from the ground. Later observations in other species confirmed the presence of tool use in nonhumans, with nonhuman primates, elephants, bears, corvids, and other animals using tools to gain food, relieve itching, or provide shelter. The current controversy stems from the question of whether animals make use of tools based on trial and error or whether they are capable of understanding the causal relation between various tools and aspects of the environment. Many studies have revealed that even chimpanzees tend to use visual cues, such as contact and proximity, rather than reasoning about support in an abstract and causal way when using tools to retrieve food (Povinelli 2000). Chimpanzees also struggle to invoke concepts of weight as a property of objects when weight can function to facilitate or hinder food retrieval (Povinelli 2012). New Caledonian crows, however, displayed an apparent causal understanding of displacement when they selected sinking objects more frequently than floating objects and solid objects more often than hollow objects to raise the water level for a reward in a study using Aesop's fable paradigm (Jelbert et al. 2014). Some, however, have shown that even humans fail to display causal reasoning in a variety of the same situations (Silva et al. 2005), suggesting that the tasks themselves are flawed.

Language

Early studies of language in nonhumans were also marred by faulty methodology. Studies in the

1960s of language in other apes first appeared promising; however, work in that area was all but squashed for many decades with Terrace's penetrating study of Nim Chimpsky (Terrace et al. 1979). Terrace showed that a chimpanzee could mimic human speech through rote memorization and operant conditioning but displayed no evidence of the hallmarks of human language use such as generativity, displacement, and arbitrariness. Terrace concluded that Nim had not acquired a skillset that deserved to be called language, as everything Nim was taught could also be acquired by pigeons via operant conditioning. Some researchers also question nonhuman apes' functional comprehension of language, as they rarely ask questions themselves, an ability that some believe distinguishes humans' capacity for language from that of nonhumans. Today, researchers have abandoned attempts to teach human-like language as a form of speech or sign language, instead using electronic keyboards presenting lexigrams to animals, such as Kanzi, the bonobo (Savage-Rumbaugh et al. 1986). Whereas some (Savage-Rumbaugh) believe that bonobos at least are capable of a human-like system of communication, most researchers are less generous in their interpretation of the results.

Theory of Mind

The question of whether nonhumans represent the mental states of other beings (i.e., ToM) is perhaps the most hotly contested topic in comparative psychology. "Scoffers" assert that no current studies can be diagnostic on the issue because all confound the use of behavior-reading strategies with the inference of mental states (i.e., mind-reading strategies) (Penn and Povinelli 2007; Povinelli and Vonk 2004). "Boosters," in contrast, have settled on the claim that many species understand at least some mental states, such as seeing, even if they do not pass false belief tests that would provide evidence of understanding knowledge states. False belief tests require the participant or animal to make an accurate prediction about how another individual will respond to a question based on what information was available to that individual. If ToM is present, the

participant will respond according to what information and experiences the other individual has, recognizing it as different from their own. However, given these limitations and qualifications, it seems clear that no other species has evolved a ToM capacity that rivals that wielded by humans to explain the actions of others. With the possible exception of experience-projection tasks, all other experimental paradigms allow the animals to predict another's behavior using behavioral cues that may or may not lead to an additional inference about underlying and unobservable mental states. Continuing to rely on such paradigms will prevent us from ever shedding light on this controversial issue, leaving comparative researchers with the onus of developing an ingenious method for testing ToM in nonhuman species in order for it to remain a viable issue within the field.

Conclusions

All of these topics are controversial because they allow researchers the potential to move the goal posts with regard to staking a claim for human uniqueness. If animals are shown to share the abilities previously attributed only to humans, humans will lose their special place at the top of evolution's metaphorical tree. However, if evolution is properly viewed as branching paths, rather than a hierarchy, the controversies will diminish. Instead of creating a dichotomy between animal minds and the minds of all other species, researchers should view each animal mind as unique and capable of its own amazing feats. Assuming that human performance should be the ultimate benchmark with which to judge the cognitive capacities of all other species leads to a slippery slope, where many species are denied the attribution of equivalent skills because researchers lack the means to inquire about their subjective experiences. Thus, many behaviors and cognitive features in nonhumans are described only as approaching those in humans, and any particular cognitive feature in nonhumans is rarely granted the full range of abilities as those granted to humans. Although highly contested in many areas, the general consensus in comparative

psychology suggests that Darwin was correct to presume some degree of continuity in mental processes between humans and other animals.

Controversial issues in evolutionary psychology

Definition

Controversies in evolutionary psychology attend two kinds of critique related to the field: *intrinsic* and *radical*. Intrinsic critiques originate from within the “Broad Church” of evolutionary psychology, and typically take the form of critiques of the Santa Barbara School, or “High Church” evolutionary psychology, with its emphasis on human universals and massive modularity and the primacy of cultural over biological evolutionary

change since the Pleistocene epoch. Radical critiques originate from outside of the field and are usually either implicitly or explicitly (in some cases) ideologically motivated. Radical critics often call into question the sufficiency of adaptationist accounts of the origin of the human mind and human behavior and frequently assert that such accounts are *ad hoc* and inherently untestable. Some radical critics substitute sociological mechanisms (such as social construction) for evolutionary ones in order to explain human behavior.

Introduction

Historically, skepticism about and controversies surrounding the prospects of evolutionary reasoning to yield a satisfactory account of the origin of human mental faculties did not relate only to proponents (and theories) of special creation, who considered evolution to be insufficient to account for the origin of any organic structure. This skepticism is also manifest in the writings of some of the earliest proponents of evolutionary theory, such as Alfred Russell Wallace (Smith 1991), who considered the “higher” faculties of the human mind too marvelous to have arisen via selection acting on variation. It is on objections to evolutionary psychology – which we define here as an empirical and theoretical approach to understanding the origin of human psychology and behavior, rooted in the idea that these phenomena are best conceptualized as outcomes of adaptations shaped by selection – emanating from ostensible evolutionists that we choose to focus this encyclopedia entry. Creationists, and their derivatives (e.g., advocates of intelligent design), while certainly qualifying as critics of evolutionary psychology (and indeed evolutionary theory writ large), simply lack sufficient representation in Western academia to be considered consequential; thus, critiques of evolutionary psychology idiosyncratic to creationism and its variants will not be considered here (for examples of these, see, e.g., Joubert 2012). Broadly speaking, the review taken up here will be subdivided into two parts. The first part will deal with intrinsic

critiques of evolutionary psychology, which originate in those who align with the objectives of the field but who have doubts about the standard model that is regnant among evolutionary psychologists. The second part will deal with radical critiques stemming from those who do not align with the goals of the field and whose criticisms are destructive, calling into question the scientific legitimacy of applying evolutionary models to the end of understanding the origins of the human mind and human behavior. As the latter set of criticisms is so large, we will examine it primarily through the writings of one adamant critic, Massimo Pigliucci, whose charges against the field are representative of standard radical critiques.

Review

Intrinsic Critiques of Evolutionary Psychology

Contemporary evolutionary psychology stems from the ethological and sociobiological movements of the twentieth century and their antecedents in the thinking of Charles Darwin, as expressed in his 1871 work, *The Descent of Man*. Evolutionary psychology has striven to distinguish itself from the human ethology movement, via its embrace of adaptationist logic, as opposed to the observational-behavioral account model, dominant in both human and nonhuman ethology (Lorenz 1965). Ethology, while evolutionarily informed, has not necessarily embraced adaptationist or *mechanistic* accounts of the origins of behavior (e.g., Tinbergen’s 1951 concept of *instinct*). Such accounts, it is argued, provide a more substantive *functionalist* explanatory framework for behavior, which in principle allows for a better understanding of the correlations among behaviors and their elicitors, in addition to the commonalities that exist among classes of behaviors. Further, positing distal mechanisms enables the construction of more rigorous hypotheses prior to the collection of data on a given behavior (be it in the context of experimental or observational work). For example, adaptationism makes sense of the phenomenon of *supernormal stimulus*, since it postulates the existence of

mechanisms that evolved to upregulate behavior in response to a specific elicitor on a dose-dependent basis; where *evolutionarily unfamiliar* levels of that elicitor exist (e.g., the stimulus is irregularly abundant in the environment), the mechanism can become overstimulated, leading to exaggerated behaviors (e.g., excessive consumption of sugar), with no throttling mechanism present to inhibit the action of the adaptation, because the elicitor was rare for the majority of a species' evolutionary history (Tinbergen 1951). By contrast, an ethological approach that restricts itself to the observation of behavior cannot explain the phenomenon of supernormal stimulus, because *post hoc* evolutionary accounts of behavior under supernormal stimulus (such as the idea that maladaptive behaviors, e.g., excessive sugar consumption, were somehow evolutionarily advantageous) absent an adaptationist-functional model are *prima facie* lacking in plausibly.

While evolutionary psychology initially very closely aligned with sociobiology (indeed the standard-bearing journal of the Human Behavior and Evolution Society was known as *Ethology and Sociobiology* until 1996), it is reasonable to consider the two as distinct fields. Sociobiology, in Edward Wilson's (1975) pioneering conception, focused broadly on the application of evolutionary and ecological thinking to understanding the origins of social behavior – not just in humans but in social organisms (such as ants) generally. Unlike early ethology, sociobiology embraced adaptationism as one of its theoretical foundations.

Conversely, contemporary evolutionary psychology more narrowly employs adaptationist logic to understand the origins of psychological modules, which are thought to have emerged in response to the presence of persistent selection pressures acting in phylogenetic time or otherwise in ontogenetic time. In order to optimize behavior, it is thought that a module must calibrate itself in response to signals stochastically sampled over the course of development (such as the modular systems that subserve incest-avoidant behaviors; Spain 1987). The multiplicity of recurrent selection pressures is said to have given rise to *massive*

modularity, i.e., the structure of the human brain as a set of modules, which are mental systems that each has a particular adaptive function (sometimes, and controversially, each such system is said to correspond to a functionally isolated neurological structure). This marriage of adaptationism and cognitive psychology is one of the hallmarks of contemporary evolutionary psychology, permitting the field to move beyond the relatively poorly articulated concept of instinct, as employed in ethology and sociobiology. The concept of modularity is intimately linked to the concept of *domain specificity*, which posits that modules require the presence of specific elicitors to produce a unit of adaptive behavior, much like the lock-and-key theory of enzymatic action, according to which an enzyme will only activate in the presence of a specific and compatible biochemical substrate. This modular specificity is necessary in order to avoid *combinatorial explosion* or the paralysis of action that would theoretically result if behavior were the product of *domain-general* processes. For it is argued that these processes would take in and combine multiple elicitors in the course of finding solutions to adaptive problems in a potentially boundless solution space, leading to exponentiation of permutation and concomitant behavioral inaction.

The Santa Barbara School

Massive modularity can rightly be considered a central tenet of the most prominent evolutionary psychology research program, specifically that which has been promulgated by John Tooby and Leda Cosmides (in particular). There are other elements associated with this so-called *Santa Barbara School* (or *High Church*; Heyes 2012) evolutionary psychology, which shape its distinctiveness as a body of theory. A key argument put forward by Tooby and Cosmides (1990) is that individual differences in personality essentially result from random quantitative variation around "species-typical" psychological adaptations, with such variation understood as a consequence of "genetic noise." One implication of this idea is that only the modules should be studied in evolutionary terms – the modules are basically

monomorphic and species-typical, having arisen due to the action of centripetal selection operating over the course of hundreds of thousands of years of exposure to recurrent domain-specific fitness challenges, unlike supposedly randomly occurring individual differences. Thus *human universals* are considered to be the optimal level at which to study human behavioral evolution. Consistent with this view, much of the foundational work in evolutionary psychology has focused on demonstrating the universality of grammar and syntax to language acquisition across cultures, in addition to factors such as kin recognition, cheater detection, and mate-choice criteria (Buss 2011).

A derivative of the human universals argument, also characteristic of the Santa Barbara School paradigm, is the *evolutionary stasis* argument. This is premised on the notion that adaptations take time to evolve since they are complex. Thus selection forming adaptations will tend to be stabilizing and centripetal (i.e., pulling inward to the mean), rather than directional or centrifugal (disruptive). Mutations are far more likely to disturb the functions of modular systems than to enhance them, and their capacity to enhance such systems diminishes in proportion to the degree to which the latter become optimized.

Humankind supposedly reached its highest point of adaptive optimization in the species' so-called environment of evolutionary adaptedness (EEA). Early on in the history of Santa Barbara School evolutionary psychology, this environment was identified with a specific time and place in the Pleistocene epoch (geographically corresponding roughly to what is today called the African Savanna; Barkow et al. 1992). More recently, the standard definition of the EEA has shifted somewhat to encompass an integrated set of spatially and temporally distributed environments in which different adaptations were acquired by different populations; but since they were universally fitness enhancing, these adaptations' fundamentals rapidly flowed to other spatially and temporally contiguous populations, ensuring their distribution all throughout the human species. There is little consensus as to when this process of universal adaptive optimization ended, though some evolutionary

psychologists suggest that it likely concluded at the start of the Holocene epoch (approximately 11,000–12,000 ybp; Kanazawa 2004). Those in the Santa Barbara School argue that evolution subsequent to this point has been purely cultural in nature but with such cultural evolutionary processes fundamentally reflecting the logic of underlying primordial adaptations. An excellent example of this thinking is found in the parasite-stress theory of values and sociality (Thornhill and Fincher 2014), which posits that many different facets of culture and inter-population variation in them, such as collectivism, conservatism, xenophobia, intellect, violence, religiosity, language, and ethnic diversity, stem ultimately from the fitness challenges posed by parasites and differential parasite burdens in and among human groups. Adaptations that were selected because of these challenges elicit in populations differing (consistent with variation in parasite burdens) degrees of *behavioral immunity*, with collectivistic, conservative, and other in-group-oriented behaviors serving to protect a cultural group from contact with members of outgroups, who may harbor novel parasites. Other behaviors, such as polygyny and consanguineous mating, may also serve to consolidate genetic capital (e.g., locally acquired immunities) within a specific group.

Explanatory models of the foregoing kind are predicated upon the idea that humans acquired a behavioral repertoire in the EEA that developed partially in response to variable exposure to parasites. Subsequent migratory radiation into different parts of the world faced distinct populations with different levels of parasite contact – thus evoking the execution of different adaptations acquired in the EEA to facilitate locally optimal behaviors. Thus, these evolutionarily informed models of cultural expression simply do not require populations in relatively novel environments to have acquired new and idiosyncratic adaptations in a relatively short period of time: their phylogenetic experience in the EEA was sufficient to biologically prepare them for a wide array of challenges, such that these populations arrived in unfamiliar environments genetically equipped to deal with (virtually) all eventualities.

Another (related) concept characteristic of the Santa Barbara School is *evolutionary mismatch*, which concerns instances in which a feature of an environment does not properly fit a given adaptive factor, such that resultantly dysregulated behaviors lead to maladaptive outcomes. Mismatch in turn depends on the idea of *evolutionary novelty* or the degree to which an environment contains potentially adaptively salient features that were either completely absent from, or were only rarely present in, the ancestral EEA. Civilization is believed to have amplified the evolutionary novelty content of environments in ways that may have led to maladaptive expression or suppression of (ancestrally) adaptive behaviors. In the Santa Barbara paradigm, the previously discussed phenomenon of supernormal stimulus may be used to explain the obesity epidemic as a consequence of evolutionarily novel availability of sugars and other “cheap” calories supernormally stimulating consummatory behaviors, along with the lack of need to hunt and forage encouraging sedentarism. Some evolutionary psychologists have applied the mismatch model to the end of understanding the origins of other diseases of modernity, both physiological and psychological (e.g., Hidaka 2012; Montgomery 2018).

Coupled to the Santa Barbara School core concept of evolutionary stasis is the concept of panmixia. As previously mentioned, genetic corridors are believed to have existed among the disparate populations living in different times and places in the EEA. The existence of these corridors permitted rapid intraspecific introgression among populations of variants that may have been universally fitness enhancing across all environments in which these populations existed (even though these variants of course originally arose at particular times and in specific locations). Variants that promote certain kinds of adaptive behavior under conditions of high parasite stress, for example, may also ultimately benefit and therefore persist in populations living under low stress, given that this parameter may vary in the future in unpredictable ways. This process would have had two primary consequences. First, it would have acted to resist *raciation* (the process by which distinct subspecies or races arise),

restricting the process to “superficial” characteristics (e.g., weak raciation producing variation in skin color across populations, adapting them to different levels of ultraviolet radiation exposure). As far as a population’s set of core psychological modules is concerned, there should exist no meaningful parametric variation among populations, in terms of either the numbers or the types of such modules (everyone recognizes kin in the same way, everyone acquires syntax in the same way, etc.). Cultural variation is therefore a consequence of differential adaptation execution under different patterns of elicitors (e.g., Thornhill and Fincher 2014). Proponents of the Santa Barbara School have even gone so far as to utilize the argument put forward by Richard Lewontin (1972) that the pattern of variance apportionment with respect to certain traits (such as blood groups) indicates greater within- versus between-race variation, to justify rejection of the possibility that disruptive selection, and resultant raciation, occurred in disparate human populations. Some Santa Barbara School proponents have also argued that the phylogenetic irrelevance of race to evolved human behavior can be demonstrated in experimental procedures that suppress the salience of race in coalition formation, once certain primes are used (Kurzman et al. 2001). The existence of panmictic patterns of gene flow in the EEA coupled with the seeming taxonomic meaninglessness of race are allegedly responsible for the apparent lack of any specialized ethnic coalition module or similar system involved in coalition formation.

Finally, another defining characteristic of the Santa Barbara School is its rejection of group and multilevel selection. The adaptationism of George Williams (1966), specifically his “ground rule,” posits that adaptive explanations of the origins of traits are “onerous,” and thus should only be utilized sparingly; similarly, individual- and gene-level selection should be favored as the most plausible mechanisms through which adaptive traits emerge, a stipulation that strongly influenced Richard Dawkins’ *selfish gene* model of selection, which in turn strongly influenced Tooby, Cosmides, and others, for whom (as with Williams) genic and kin selection constitute *sufficient*

driving forces behind the evolution of psychological modules.

Critiques of the "Standard Model"

The Santa Barbara School paradigm is sometimes described as the standard model of evolutionary psychology by its critics within the field (Winegard et al. 2017). Each of the core tenets of the standard model has in fact been vigorously and constructively critiqued by various researchers who align with the basic objectives of evolutionary psychology and who are here said to constitute the *Broad Church* of the field.

Massive Modularity on the Chopping Block

Massive modularity, and the adaptationist assumptions that undergird it, is one of the more frequently critiqued pillars of the standard model. It has been noted, for example, that the existence of *heritable* and substantial individual differences in the domains of personality and cognition along with the presence of genetic correlations among seemingly distinct sources of those differences (such that a *General Factor of Personality* [GFP] and a *general factor of intelligence* [g] seem to dominate the variance in "performance" among specific measures of personality and cognitive ability; Jensen 1998; Muek 2007) strongly militate against the particularist and monomorphic approach to understanding the origins of cognitive and conative faculties in the standard model. It has been noted that the definition of "module" appears to be elastic in such a way that permits the concept to simply be redefined so as to suit the needs of the field at any given time. This was the thrust of Jerry Fodor's (2000) critique of the standard model's massive modularity. Fodor (1983), who developed the mature form of the modularity concept, defined modules in a highly specific way, and argued that they exclusively appear in so-called peripheral mental systems (such as those subserving sensory perception). On Fodor's (1983) view, modules are characterized by (among other features) the quality of *encapsulation* or the specificity of a given module's association with a given eliciting stimulus. Fodor further argued that beyond this handful of very basic modules, there exist

domain-general systems that are responsible for all forms of higher-level processing. Fodor notes that subsequent attempts to "salvage" massive modularity appear to have moved beyond this more restricted conception of encapsulated modularity by recasting modules as entities that can interact with other modules in order to construct the more elaborate sorts of circuits needed for solving more complex problems based on context (e.g., Barrett and Kurzban 2006). David Geary (2005) observes that there is a decided lack of coherence in defining modules and reviews several seemingly distinct definitions in his seminal work on the evolution of general intelligence. Others (Fodor 2000; Panksepp and Panksepp 2000) have argued that if any mental system can be classified as a module, then the module concept is useless. Panksepp and Panksepp (2000) have even proposed a sort of *anti-modularity*, based on the idea that the brain is comprised of highly plastic and open-ended systems that did not evolve to solve specific tasks, but can nevertheless be organized into different systems that are optimized for producing certain behaviors or solving certain problems. It was this *domain-general* capacity of the brain that was primarily subjected to selective pressures across various adaptive contexts, rather than solution-generating subsystems, as the standard model posits.

It has been further argued that the dominance of general factors in distinct domains of life history, personality, and cognitive ability strongly evidences the existence of domain-general processing systems, which act to contextualize problem-solving via the use of learning and conditioning pathways, in addition to the establishment of hierarchical goals as guides to action (Chiappe and MacDonald 2005; Figueredo et al. 2006; Geary 2005). Systems such as working memory in the case of higher-order cognition and executive functions broadly in the case of higher-order conation have been put forward as solutions to both the combinatorial explosion and poverty of stimulus arguments against the existence of domain-general processing systems. These *executive* systems permit the solution space for a given open-ended problem (i.e., one for which there is no preprepared response) to be

restricted based on trial-and-error experience and concomitant learning and also intrinsically generated goal states, thus essentially throttling the ability for *representations* (i.e., the outputs) arising from more fundamental and specialized cognitive systems to proliferate and combine in uncontrolled ways. The resultant *meta-representations*, which guide behavior, can therefore be thought of as the equivalent of battle plans chosen by a general (the executive cognitive and conative systems) from among a set of potential plans, which in turn were prepared via consultation with military specialists (the lower-order, more domain-specific systems). The generals in this scenario are not inundated with countless battle plans, as ultimately they choose one from a subset, which is itself limited via a filtration process involving the general's staff consulting only the relevant specialists (e.g., if an enemy country possessed chemical weapons, then only chemical weapons specialists would be consulted, there being little point in talking to, say, nuclear weapons specialists). The failure of a given battle plan would occasion the development of new plans, only in this instance the particulars of the failure would be taken into consideration, imposing an additional constraint upon the solution space (a process analogous to trial-and-error learning). The general in this analogy further has a specific goal state (military victory), which imposes yet another constraint upon the broader solution space (the general would not, e.g., plan to build a circus in the town square if his objective is successfully defeating a foreign enemy). The goal state is flexible, however, as different strategies (sub-goals) can be tried and discarded based on their efficacy.

Some evolutionary psychologists have attempted to delimit these domain-general processes as modular in nature and therefore pertaining to specific adaptive problems. Dan Sperber (1994) has proposed the existence of a *metarepresentation module*, the function of which is to specifically deal with organizing the behavior of lower-order modular systems (akin to the general of the previous example). Satoshi Kanazawa (2004) has proposed that general intelligence is itself a module adapted to dealing with domain-

specific problems associated with evolutionary novelty. These attempts to modularize open-ended processes to a degree serve to highlight Fodor's and others' aforementioned objections – chiefly that if “everything” is a module, then “nothing” is, as there is now so much conceptual elasticity that the idea of a module loses coherence and thus scientific utility.

Such attempts furthermore suffer from the *poverty of stimulus* problem, as the sorts of problems that improvisation is needed to solve do not adhere to a specific domain *per se* but tend to straddle multiple domains. It is therefore unclear how stimuli related to such problems could be treated as pertaining strictly to a specific domain, and so it is difficult to see how these stimuli would yield dedicated systems for solving those problems. Put succinctly, the stimuli, by virtue of being indiscriminate with respect to domain, would not occur relative to *any specific domain* in isolation frequently enough to favor the evolution of specialized solution-generating mechanisms. The postulation of domain-general processes avoids the poverty of stimulus problem, however, as such processes simply act to impose boundary conditions upon the sorts of representations that can be usefully combined into units of behavior. Domain-general processes never evolved to deal with a given domain *per se*; instead, they confer a fitness payoff whenever a unit of behavior yields a successful solution to a given problem for which an organism is simply not prepared through some more specialized mechanism. The domain-general processes interact with the specialized ones but are not fully reliant upon their representations as guides to behavior (indeed systems of the former type can actively override *implicit* behavior originating from lower-level systems, when such overriding serves some explicit goal; a good example of this process would be the use of executive functioning in modulating impulsivity among those with low time preferences, facilitating delay of gratification; MacDonald 2008). This should not be taken to imply that there is some overarching *central executive* system in place that coordinates all behavior either; indeed, there is evidence for the existence of at least two broad executive

systems, one dealing with cognition and one dealing with conation (including life history and personality), which are largely genetically distinct from one another (Woodley of Menie and Madison 2015). This distinctness could be considered a kind of *metamodularity*, as it implies that the brain organizes behavior much like how the various branches of government organize the activities of a state: there are very broad but ultimately finite domains to which each domain-general system (or branch of government) pertains, which can be dealt with by each domain separately and largely without the need for interaction between them (Woodley 2011).

Supporters of the standard model (Cosmides and Tooby 2002) have also attempted a solution to the problem of the appearance of domain-general systems (at least as they pertain to cognition), by drawing a distinction between *dedicated* and *improvisational* intelligences – the former composed of modules and their domain-specific solutions to domain-specific problems and the latter representing the sum of the outputs of various modules that act in concert in response to all of the domain-specific components of a seemingly domain-general problem. Based on this model, behavioral units are consequences of an essentially harmonious interplay among the action of many modules, refined by selection. This solution obviates the need for domain generality, as (presumably) suboptimal behaviors, resulting from disharmonious interactions among modules, would have been selected out of the population. Behavior, furthermore, constitutes the level at which the representations are “integrated,” negating any necessity for “dedicated” domain-general systems to produce metarepresentations for guiding behavior. This model posits a process analogous to playing the piano. Each key is dedicated to the production of a limited range of sounds. The striking of keys is analogous to domain-specific elicitors, and the range of notes is analogous to the breadth of domain-specific problems. The resultant notes can be combined into either harmonious or disharmonious configurations, depending on which set of keys is struck and in what order. A key problem with this model is that it implies that the appearance of domain-general

mechanisms among psychometric measures of cognition and conation are illusory, resulting from the harmonious combination of modular “keys” being “played” by exposure to a given set of domain-specific problems. This implies that different problems yield only superficially similar latent factors, based on the different “scores” that characterize each problem domain. Thus we would not expect *g* factors, for example, to be measurement invariant across problems (which they typically are) nor would we necessarily expect hierarchical factor models to suffice for modeling higher-order variables among psychometric data (instead we would expect some kind of correlated factor model to be a better fit, which, at least in the case of intelligence, is not the case; Johnson et al. 2004). These psychometric observations imply the existence of distinct, higher-order, and domain-general processes, which regulate the production of behavior, and serve as an intermediary between more specialized systems downstream and behavioral action units upstream of them.

An additional problem with massive modularity issues from the observation that domain specificity implies species typicality, i.e., each species is adapted to the contours of a unique evolutionary niche or EEA. Thus behavioral differences among species should be differences of *kind* rather than *degree*. This has led to certain animal ethologists (e.g., Herrmann et al. 2010) positing that the patterns of domain-specific mechanisms involved in solving cognitive problems differ among species in such a way that makes them incomparable, when individuals of different species are challenged using common behavioral probes. Thus “intelligence” does not stem from some set of processes common across taxa but instead differs based on the unique phylogenetic experiences of different taxa. This claim has been countered with the observation that species differ from one another in problem-solving capacity primarily with respect to a latent general intelligence-like (*Big G*) factor, rather than relative to specialized problem-solving abilities (Fernandes et al. 2014). Furthermore individuals of different species manifest the largest differences in performance on cognitive measures that exhibit both high loadings

onto a common g factor and also high phenotypic variability, with the differences obscured by the presence of abilities that are modularized in one species but not in another (and thus impose floor or ceiling effects on performance, reducing variability; Woodley of Menie et al. 2017a). Highly G - and (at the individual-differences level) g -loaded measures exhibit the strongest signals of having been under directional selection (Fernandes et al. 2014; Woodley of Menie et al. 2015), so selection appears to have arrayed species differences in intelligence along a continuum of performance with respect to some overarching faculty (which derives from a quality common across taxa), rather than relative to specialized modules (species differences on such modules do exist; however, they are not the main locus of these differences in the context of cognitive performance). These findings raise further questions concerning the uniqueness of human modules. Implicit in the standard model is the assumption that humans acquired specialized adaptations to problems that were unique to human evolution. This is illustrated in the case of human language acquisition ability, which has been held up as an archetypal human species-typical module (Pinker 1994). But since this mechanism was first described in the literature, evidence has accumulated indicative of communicative ability and even primitive language use among other taxa and also prehuman ancestors (Clark and Henneberg 2017). This suggests that, while language use evolved in a particularly elaborate way in humans, the capacity to acquire and use structured language is something that an array of taxa potentially enjoys. Human species-typical modules therefore may not be uniquely human, strictly speaking, but may instead be derived from ancestral structures, which many taxa share (Panksepp and Panksepp 2000).

Individual Differences Are Evolutionarily Significant

One of the weakest features of the standard model is the claim that individual differences arise only from ontogenetic as opposed to phylogenetic processes, specifically resulting merely from “genetic noise.” This claim could be said to have

simultaneously stemmed from a desire to rhetorically highlight what Tooby and Cosmides perceived to be the major locus of human evolution, i.e., the fundamental architecture of the adaptive structures guiding behavior, coupled with the (now believed to be flawed) idea that adaptations should exhibit little heritable variation because selection has depleted it (Fisher 1930).

Nevertheless, many researchers believe that individual differences have adaptive significance. Certain evolutionary psychologists have attempted to square the existence of heritable individual differences with massive modularity, such as Geoffrey Miller, who considers individual differences, and also genetic correlations among different sources of individual differences, to result from the action of pleiotropic mutations, which jointly influence the efficiency with which multiple modules can act, bringing the resultant variations into correlation with one another. Different levels of these traits in different individuals would therefore reflect variation in mutation load. These differences serve as indices of genetic quality, guiding mate choice under sexual selection. The pleiotropic manifolds among traits not only potentially account for the presence of g and the GFP but also imply the existence of a broader general fitness factor (f) superordinate to multiple psychological and even physiological domains (Miller 2000).

Various evolutionary psychologists (most notably J. Philippe Rushton [1985] and Aurelio José Figueredo and co-workers [2007]) have also used life history theory to account for interindividual trait variation. Life history theory is based on the idea that organisms tradeoff bioenergetic and material resources among trait domains in order to optimize their fitness given exposure, over phylogenetic and ontogenetic time, to different degrees of environmental risk (harshness and unpredictability). Organisms living, and/or evolved, in environments characterized by high levels of, and/or random, mortality tend toward replacing lost offspring (mating effort) at the expense of investment into offspring (parenting effort), investment into condition-maintenance (somatic effort), and investment into inclusive fitness (communitarian effort).

Low and/or predictable mortality regimes on the other hand favor high levels of parental, somatic, and communitarian effort. Personality and another dimension of conation (the *K*-factor) that tracks variation in a number of psychological and behavioral components of life history cohere genetically into a continuum termed the Super-*K* factor, which also includes indices of physical and mental condition (collectively termed covitality). The *fast* life history pole of this continuum is reflected in poor general health and low social effectiveness, as well as risk-taking, promiscuity, weak attachment, poor executive functions, and concomitantly poor forward planning and impulse control. Those at the *slow* end by contrast are typically high in general health and social effectiveness, and are also altruistic, sexually and behaviorally restrained, prosocial (high need for attachment), future oriented, etc. Life history theory does not dispense with modularity (modules are ever present in the background). But unlike fitness indicators theory, which posits that individual differences are *purely* byproducts of variation in loads of adaptation-degrading mutations, which are acted on by sexual selection and with high *f* being *universally* favored over low *f* across environments, life history theory postulates that different levels of *Super K*, as reflected in patterns of variation and even degrees of coordination among modules (regulated through higher-level domain-general systems), yield different selective benefits under different regimes of environmental risk (Ellis et al. 2009). What both models have in common is the view that individual differences are ultimately maintained by various forms of stabilizing selection.

Woodley (2011) has taken the argument for adaptive individual differences even further by positing that the niche splitting that results from the presence of individual variation is itself highly favorable to the success of *competing groups*, as greater division of labor permits the sustainment of greater population densities, in addition to conferring upon groups a greater relative advantage in competition. Kevin MacDonald (2008, 2009) has elaborated this *anti-Williamsian* model further

still in his work on *cultural group selection*, which posits the existence of certain sources of individual variation that facilitate maintenance of the integrity of the extended phenotypes of cultural groups through suppression of free-riding behaviors. An example of such a source of variation would be *effortful control*, or the ability to use explicit processing to override implicit drives, which, if left unchecked, may promote behaviors that would undermine the integrity of a group's extended phenotype. Those high on effortful control can furthermore run strategic interference on those low in the ability, via the imposition of sociocultural conditions conducive to the fitness of those with group-selected (i.e., group-fitness enhancing) traits.

Race and Population

The broader debate about the role of group selection in human evolution ties into the related issues of whether (a) population structure (i.e., human racial and ethnic diversity) has played a meaningful role in human evolution and (b) whether environments that humans encountered after "leaving" the EEA were evolutionarily significant. If, as the standard model posits, racial and (biological) ethnic divisions were absent from the EEA, then ethnic conflict becomes difficult to explain. As Salter and Harpending (2013) demonstrated, kinship is a relative value: two randomly selected individuals from a single population may be only weakly related to one another in absolute terms, but relative to a third individual, selected from a more genetically distant population, they may be related to one another much more closely, when their coefficients of ethnic kinship are quantified with respect to their relatedness to the third individual. Thus potentially very large fitness pay-offs can accrue from the use of racial and other ancestral markers in the formation of coalitions for the purpose of intergroup conflict. These markers are typically highly correlated with one another, with only small numbers of them needed to infer ancestry with an extremely high degree of confidence. Edwards (2003) showed how using only small numbers of correlated traits it is

possible to highly accurately assign racial ancestry to individuals. He presented this finding in contrast to what he termed *Lewontin's Fallacy*, the idea that race is not a meaningful biological concept because there is more genetic variation within than between racial groups. Lewontin's (1972) "deconstruction" of the concept of biological race involved emphasis on single loci associated with systems that have been under persistent stabilizing selection (such as the ABO blood group system). In selecting such single loci, variation due to population structuring (racial or otherwise) will naturally be suppressed. These facts do not contradict Lewontin's accurate claim that as a general rule there is more genetic variation within than between racial groups (consistent with this, *Fst*, or the proportion of the variance among humans that is due to population structure, is around 15%; Cavalli-Sforza et al. 1996); but they do strongly counter his inference from this observation that race is not a valid biological or taxonomical category.

Some have also questioned the idea that race and population structure more generally have played no role in human evolution. Harpending (see MacDonald 2001, p. 70) has posited the *starburst model*, which is based on the notion that distinct populations repeatedly expanding, coming into conflict, and retreating were likely recurrent features of human evolution. Phylogenetic integration across these encounters should have prepared humans with adaptations that cause them to factor perceived genetic similarity into coalition formation. This is not to say that population-level variation and even context specificity do not play a role in how these mechanisms express in different groups. Some populations tend to be more collectivistic than others; thus, for these groups the salience of ethnic cues to coalition formation may be higher (MacDonald 2001). Ecological stress and pressures favoring endogamy for the purpose of boosting homozygote advantage, such as that experienced by populations under high parasite load, may also serve to epigenetically upregulate the salience of

ethnicity to coalition formation. That ethnicity matters to coalition formation across a very broad swath of *natural* contexts is a robust finding, however (Salter and Harpending 2013; MacDonald 2001).

Rapid Genetic and Cultural Variation: Beyond the EEA

Finally, the existence of genetic variation, across space and time, that is continuous with cultural variation (as studied under the rubric of *cross-cultural sociogenetics*) casts the standard model's concept of the EEA into doubt, since this variation implies that there were in fact multiple environments of evolutionary relevance for different populations and that the assumption of panmixia simply has not held throughout human evolution (otherwise *structured* population differences would not exist). This further indicates that cultural variation is not disconnected from genetic variation among populations, and may even be a motor for such change, as is posited by the theory of *culture-gene coevolution* (Cavalli-Sforza and Feldman 1981). Based on this model, culture changes in response to shifts in the gene frequencies of the populations responsible for generating it. As populations become more intelligent or more altruistic, for example, the contours of the culture change, reflecting such shifts. Those changed contours will in turn create additional opportunities for adaptive evolution, as the presence of certain cultural practices may impose fitness penalties upon one group of individuals with one set of traits while promoting the fitness of another group.

Cultural complexification was a hallmark of Eurasian populations living during the Holocene, for which genetic data indicate rates of adaptive evolution that were on the order of 100 times faster than those during the preceding Pleistocene epoch (Hawks et al. 2007). Evidence has been found that genetic variants associated with general intelligence were under particularly strong positive directional selection in the period covering the Bronze Age to approximately the mid-nineteenth century (Woodley of Menie et al.

2017b), with selection having subsequently disfavored these variants (due to the action of so-called *dysgenic selection* stemming from the use of contraception and fertility delays among those exposed to education for the longest amounts of time; Lynn 1996), starting in the mid-nineteenth century and continuing into the present day, at least in Western nations (Kong et al. 2017; Woodley of Menie et al. 2017d). The extremely rapid pace of culture-gene coevolutionary change and (resultant) cultural complexification among Eurasian populations in particular makes Holocene environments highly relevant to understanding human evolution (Frost 2011). Frost (2011) notes that the basic set of adaptive modules may have come to vary across populations – new ones having arisen rapidly via the process of duplication. He gives as an example of an outcome of this process the *visual word form area* of the brain, which permits written words to be easily recognized as such and likely arose as recently as 6,000 years ago, concomitant with the origins of written language among nomadic agriculturalists living in the Arabian Peninsula. The existence of these processes by which new adaptations can develop rapidly, essentially deriving from the duplication of already existing adaptations, furthermore contradicts a key assumption of the standard model, namely that such structures must take tremendous amounts of time to evolve, being fragile and sensitive to the action of deleterious mutations. In fact, these observations of apparently recent and rapidly evolved adaptations may pose the most profound challenge to the Santa Barbara School model, as the rapid emergence of entirely new adaptive systems in very small frames of time suggests that the basic claim of the universality of modular architecture among humans needs to be substantially revised. As Nicholas Wade has observed, “[n]ew analyses of the human genome have established that human evolution has been recent, copious, and regional” (2014; p. 2). It is therefore imperative for the Santa Barbara School of evolutionary psychology, if it wishes for its paradigm to survive, to consider ways of reconciling this profusion of new findings with its own position.

Radical Critiques of Evolutionary Psychology

Discussion of evolutionary psychology outside of the field is not infrequently critical. A significant subset of “external” critiques of the field is extreme, maintaining that evolutionary psychology, either necessarily or as standardly practiced (i.e., consistent with the Santa Barbara School model), is theoretically, methodologically, and/or empirically illegitimate. These are here termed *radical critiques* of evolutionary psychology. Pigliucci (2010, pp. 41–45) offers one such attack on the discipline, which he calls a “quasi-science” (p. 24), in other words a field of research that is located somewhere between actual science and pseudoscience. Pigliucci’s case against evolutionary psychology is exemplary of the larger class of radical critiques, insofar as it rests upon common and basic misunderstandings and mischaracterizations of research and methods and even upon unequivocally false claims about the nature of particular scientists’ work. In the way of outright inaccuracies, for instance, Pigliucci (2010, p. 41) insinuates that Herrnstein and Murray’s *The Bell Curve* (1994) is a work of sociobiology, which is in turn related to evolutionary psychology, despite the fact that the work involves almost no discussion of evolutionary theory and instead draws primarily on psychometrics; further, he asserts that *The Bell Curve* is “intellectually questionable” and makes “unsubstantiated claims about genetic determinism of human cognitive traits,” claims which are simply untrue (Herrnstein and Murray’s [1994] discussion of evolutionary theory is almost entirely relegated to a short section in an appendix, which discusses J. Philippe Rushton’s differential *K* theory of race differences. The discussion consists mostly of a general overview of Rushton’s theory and the controversy that has surrounded it, together with Herrnstein and Murray’s conclusion that “the theory remains a long way from confirmation” [1994, p. 643]. This hardly constitutes reliance on evolutionary theory. Furthermore, *The Bell Curve* contains minimal discussion of the genetic bases of intelligence, offering merely the view that variation of intelligence, among individuals [p. 292] and groups [p. 311], is due [or is probably due, with respect

to intergroup variation] to both *genetic and environmental* differences. At least in the case of individual variation, this is uncontroversial among experts [e.g., Plomin and Deary 2015]. Moreover, a report published by the American Psychological Association shortly after *The Bell Curve*'s publication largely supported the book's central claims [Neisser et al. 1996], indicating that Herrnstein and Murray's [1994] theses did not offend the mainstream of psychological research. In any case, Herrnstein and Murray [1994] clearly did not endorse genetic determinism as traditionally conceived, since they did not deny a role to environmental factors in the determination of individual and group differences. Even if they had, however, it should be noted that Pigliucci [2010] is mistaken in his apparent belief that the study of the relative contributions of genes and environment in determining human traits, cognitive or otherwise, is part of evolutionary psychology or theory. In fact, this is the province of a separate field: behavioral genetics [which is, to be clear, obviously compatible with evolutionary psychology, but is, as stated, independent from it].)

In tackling evolutionary psychology directly, Pigliucci (2010) employs the familiar gambit of averring that human behavior has been of course shaped by selective pressures, and yet concluding that it is nonetheless impossible to ascertain much about *how* human behavior evolved (Richardson 2007, p. 95 expresses the same sort of idea). He offers three arguments for this view. First, in criticizing Randy Thornhill and Craig Palmer's evolutionary account of rape, he argues, without evidence, that rape "doesn't pay," i.e., does not contribute to fitness, "in today's society" (p. 42). The fact that a behavior is not adaptive in a contemporary context does not imply that it was not adaptive in the past, however, and evolutionary psychologists, including Thornhill and Palmer, usually refer to conditions of the distant human past to explain the context in which human traits emerged because they were adaptive. Further, it is often not difficult for evolutionary psychologists to identify the features of modern environments that render maladaptive some trait predicted to have been adaptive, such that it

becomes clear that trait would be adaptive if not for those features (see, e.g., Kanazawa 2003). That notwithstanding, it would be very odd indeed for evolutionary theories of human behavior to focus exclusively on contemporary circumstances.

Apparently realizing this shortcoming, and implicitly acknowledging that his first argument is beside the point, Pigliucci (2010) then maintains that evolutionary psychological theories invoking evolutionarily relevant features of humanity's past, specifically in the Pleistocene, depend on mere "just-so stor[ies]" – such theories cannot find adequate empirical substantiation because "behaviors have an annoying tendency not to leave a fossil record, and neither do the details of the (largely social and cultural) environment under which [natural selection allegedly operated on humans]" (p. 43). The charge that evolutionary psychologists tell just so stories has been frequently advanced since the emergence of the field, and despite evolutionary psychologists' many refutations of the accusation (e.g., Andrews et al. 2002 and a number of commentaries on the piece), radical critics repeat the complaint, usually, as in the case of Pigliucci (2010), with no effort to rebut evolutionary psychologists' replies. Evolutionary psychologists, whether of the Santa Barbara School variety or otherwise, are in fact at pains to make their models of humanity's past circumstances consistent with available archaeological, anthropological, and paleontological evidence (e.g., Bowles and Gintis 2011), even if their emphasis on the Pleistocene is sometimes excessive and comes at the cost of ignoring recent human evolution (as was argued earlier in this entry). Beyond this, it must be noted that the idea that evolutionary psychology uniquely suffers from the problem of just so stories is grossly unfair. As Andrews et al. (2002) observe, a just so story is simply an inadequately empirically supported scientific claim. The non-biological social and human sciences and related fields, e.g., social psychology, cultural anthropology, sociology, and gender studies, are far guiltier of telling just so stories than evolutionary psychology has ever been. Specifically, they tell utterly implausible just so stories in which only social

and cultural constructions are treated as germane to and invoked to explain human behavior (or at least human behavioral variation), even though about half a century of quantitative behavioral genetics (Polderman et al. 2015) and in more recent years molecular behavioral genetics (e.g., Kong et al. 2017) have left no reasonable doubt that such sociocultural determinist models are untenable. Yet these non-biological behavioral disciplines are almost never met with the charge of telling just so stories. Pigliucci (2010) certainly does not claim that they are borderline pseudosciences. But in the judgment of Tooby and Cosmides (1992), these fields operate in the grip of the so-called *Standard Social Science Model* (or SSSM), a scientifically illegitimate, and thus critique-worthy, explanatory framework positing that biology is largely irrelevant to human behavior and culture or at least to variation in these phenomena. More precisely, the SSSM holds that human behavior should be understood as something developed and learned purely through environmental input – given the model’s assumption that the brain comes largely or entirely without predispositions toward the generation of particular behaviors – and further posits that society and culture should be analyzed exclusively on their own terms, meaning that biological factors should not be construed as if they undergird or give rise to social and cultural phenomena. It could be argued that Tooby and Cosmides’ (1992) description of the SSSM at times shades into caricature, since even the behaviorists did not deny that the human brain is equipped with certain psychological-developmental predispositions. Still, the tendency of social scientists to disregard pertinent research in the life sciences and its implications, and to stubbornly insist on the basic contingency and flexibility of human social and cultural activity with no or minimal explicit awareness of the limits that biology imposes on these domains, is repeatedly demonstrated by Tooby and Cosmides (1992), as well as by the contemporary academic literatures of the social sciences.

With respect to Pigliucci’s (2010) fossil claim, if it were indeed true that evolutionary accounts of human behavior cannot be reconstructed without

an appropriate fossil record, it would follow that evolutionary accounts of nonhuman animal behavior are impossible. This would invalidate a great deal of evolutionary biology, primatology, and entomology, to name a few fields. Pigliucci’s (2010) second argument clearly “proves too much,” then.

Yet again, however, Pigliucci (2010) seems to tacitly admit that an argument of his is not actually effective. For he notes that sound evolutionary theories of nonhuman animal behavior *can* be developed despite “lack of a relevant fossil record” (p. 45); but he also thinks that a special fact about humans entails that the same cannot be done for human behavior. This fact is that there are not enough surviving species of sufficiently close phylogenetic relation to humans with which humans can be compared, so as to gain insight into human behavioral evolution. The limited number of surviving related species means that the “statistical power” of such comparative efforts would be insufficient (Pigliucci 2010, p. 43). This is another argument that entails, if Pigliucci’s (2010) standard of close phylogenetic relatedness were applied, that much of the work in an established evolutionary science that Pigliucci does not criticize is worthless, for it would suggest that the evolution of primate behavior in general, an important area of study in primatology (e.g., Burkart et al. 2017), should be inscrutable.

Moreover, Pigliucci (2010) betrays a poverty of methodological imagination and theoretical sophistication in maintaining that evolutionary behavioral hypotheses can be tested only via interspecies comparison and experiments and observational studies in species’ EEAs (p. 45). First, the study of surviving hunter-gatherer tribes likely gives valuable, though imperfect, insight into the nature of human Pleistocene life (e.g., Diamond 2012) (note that the extent to which contemporary nonhuman animals’ environments are reflective of earlier environments in their phylogeny, to which they may be more optimally adapted, is not always clear; the existence of general intelligence, a capacity that is adaptive insofar as it allows organisms to deal with evolutionarily *novel* problems, across a number of species strongly evidences that they have not lived in completely

invariant environments over time [Burkart et al. 2017], as was discussed in the previous section). Second, the distorting effects of modern environments on human behaviors can be largely sidestepped by comparing various human *populations* inhabiting vastly different physical and sociocultural environments. When the same behaviors are found in sufficient frequency across these environments, and if they are shown to be generally adaptive, there is strong evidence that they are part of humans' *broadly* universal adaptive architecture (the case for evolutionarily tying such behavior specifically to the Pleistocene would require evidence that it emerged or at least existed among humans of that epoch for adaptive reasons, which may come from the sources indicated earlier, especially archaeological and paleoanthropological studies; see Gintis et al. 2015 for an example of a paper that builds a model of human behavioral evolution partially through application of such sources of evidence). Additionally, the seemingly anomalous behavioral phenomena seen in modernized human environments are not always as contrary to evolutionary psychologists' theories as some radical critics believe, meaning that they do not necessarily pose insurmountable obstacles to the application of evolutionary theorizing to modernized humans' behavior. For example, although social status is, contrary to some sociobiologists' and evolutionary psychologists' theoretical expectations, *negatively* associated with fertility in modernized women, certain data indicate that it positively relates to fertility in modernized men, and some have argued that these relationships between fertility and social status in men and women are not out of keeping with evolutionary models and observations of behavior in pre-industrial societies (e.g., Hopcroft 2015; cf Kanazawa 2003). Similarly, intelligence has a negative rather than the expected positive relationship with fertility in modernized populations; nonetheless, intelligence is still positively related to other measures of biological fitness, such as survival, in modernized humans (Burkart et al. 2017, p. 54). The anomalous negative correlation between intelligence and fertility in modernized populations nonetheless can be potentially

accounted for without violating the standard assumptions of evolutionary psychology (e.g., Kanazawa 2014). And contradicting the false but common charge that evolutionary psychologists think that all human behavioral phenomena can be explained in terms of adaptation, a theory has even been propounded to account for the fertility-depressing behaviors found under conditions of modernity with reference to the accumulation of *deleterious* mutations that specifically target and degrade adaptive behaviors and cultural structures (Woodley of Menie et al. 2017c).

Given Pigliucci's (2010) tendency to offer criticisms of evolutionary psychology that in fact call into doubt a number of evolutionary sciences, a further and more general point must be considered: Radical critics of evolutionary psychology are often not merely opponents of evolutionary psychology *per se* but of *adaptationism* as more broadly construed in biological science. Hostility to adaptationism was perhaps most famously expressed by Gould and Lewontin (1979), from whom Pigliucci (2010) borrows the just so stories criticism – in the case of the former, however, this criticism *explicitly* applies to adaptationist explanations in evolutionary science as a whole. Adaptationism can be defined as a mode of biological inquiry in which *some* features of organisms are hypothesized to be evolutionary responses to problems organisms' ancestors faced in the course of phylogenetic development. Without question, adaptationism is the most successful theoretical perspective on evolution in biological science, whereas non-adaptationist programs emphasizing genetic drift or Gould and Lewontin's (1979) "exaptations" have achieved nothing meaningful in advancing understanding of the evolution of life on earth (see Figueredo and Berry 2002; Krasnow and Truxaw 2018). As Figueredo and Berry (2002) ably show, the concept of an "exaptation," i.e., a trait that evolved to serve one adaptive purpose in one environment and then came to serve a different purpose in a different environment, reflects nothing other than basic misunderstanding of the concept of adaptation. Insofar as a trait's adaptiveness is always determined relative to some environment, the "exaptation" idea is already implicit in the original

adaptation concept. “Exaptationism” therefore adds nothing to biological knowledge. Adaptationism’s success is due to the fact that it alone (as an evolutionary paradigm) is able to produce novel predictions and theories that advance evolutionary understanding, for only adaptationism can link environment and ecology to phylogenetic development in such a way that the former can *explain* the latter (for a very similar point, see Krasnow and Truxaw 2018). At best, non-adaptationist perspectives can be applied when adaptationist hypotheses fail and in that case are merely part of the adaptationist program. At worst, non- (or even anti-) adaptationism is simply a way of retarding progress in biological science, often for political reasons, as when Levins and Lewontin (1985) sought to make evolutionary biology compatible with the pseudoscience of Marxism. Ironically, for all his objections to adaptationism as poor science, Lewontin’s non-adaptationist biology never advanced beyond a thin pretext for political advocacy (Wright 1998). In evolutionary psychology, adaptationism has proven remarkably successful, with a number of ambitious theories having offered testable predictions that have been found to be consistent with relevant empirical data (e.g., Loehlin et al. 2015; Woodley 2011). It is difficult to explain how such theories have made so many accurate predictions if the state of nature is such that, as Pigliucci (2010) claims, human behavioral evolution is simply beyond researchers’ grasps.

Conclusion

This entry has examined two forms of critique of evolutionary psychology, intrinsic and radical, and prominent controversies that are connected to them. Critiques of the former variety proceed from the premise that evolutionary theory can be successfully employed to elucidate the human mind and human behavior but maintain that particular forms of such evolutionary psychological science are flawed. Therefore intrinsic critiques are *constructive*, aiming to eliminate error in evolutionary psychology. Conversely, radical critiques of the field are *destructive*: their purpose

is to demonstrate that evolutionary psychology does not or even cannot qualify as a bona fide science. It is difficult to find fault in intrinsic critique *as such*, since it is an ordinary feature of all sciences. But radical critique requires substantial rational warrant, especially when its target is a well-established field of intellectual endeavor.

It is apparent that radical critics of evolutionary psychology have not met this burden, mostly because of their reliance on misrepresentations of the state and practice of evolutionary psychology and on standards of evidence that are unreasonable for all social scientific and some biological areas of study. Unless one is prepared to cast aside most or all of archaeology, paleoanthropology, environmental history, and so on, it is clear that approximately true reconstructions of the phylogeny of modern humans and their hominid ancestors can be and have been developed (see Bowles and Gintis 2011; Gintis et al. 2015). These reconstructions allow scientists to gain knowledge about the selection pressures that have shaped these phylogenetic pathways, and such knowledge in turn serves as the fundament of evolutionary psychological theorizing. When academics such as Pigliucci attempt to impose arbitrary standards of evidence that would have us ignore everything not known with a certain high level of precision, and thereby absurdly exclude as scientifically illegitimate multiple areas in the life sciences, one is rightly suspicious. Suspicion grows once it is observed that critics of Pigliucci’s, and by extension Gould and Lewontin’s, ilk never seem compelled to criticize strikingly empirically weak social sciences that endeavor to explain human behavior (e.g., sociology, social psychology, and political science). For reasons not made explicit, evolutionary psychologists are under obligation to test their claims using the highest-precision methods on offer in the evolutionary sciences, and if these methods cannot be applied in studies of humans, *nothing* less rigorous is acceptable (so says Pigliucci). On the other hand, sociologists and social psychologists are free to proceed, as they almost always do, on the (implicit or explicit) assumption that biological factors are either irrelevant to human behavior or are of such trivial import that they

can be safely ignored. But surely if Pigliucci were right, the inscrutability of the evolutionary, and therefore (to a great degree) biological, forces underpinning human behavior should lead to persistent and irresolvable doubt about why humans behave as they do. Sociological disciplines, by virtue of their inability to disentangle the evolutionary/biological from the social (given, again, that according to Pigliucci the former is scientifically inaccessible in the case of humans), should be just as powerless to illuminate human behavior as the evolutionary behavioral sciences. Perhaps limited proximate-level sociological and social psychological science would still be possible, but certainly the more encompassing and distinctive theories would have to be abandoned. So why have Pigliucci, Gould, Lewontin, and other such radical critics of evolutionary psychology abstained from attacking sociological theorists and scientists?

The most plausible answer to this question appears to be that radical critics are almost all allied to left-wing political causes, to an extent that has distorted their scientific work. Gould and Lewontin's Marxism and its deleterious effects on their "scientific" output are well known, and probably constitute the major reason that many biologists typically regard their pronouncements, as they pertain to human nature, with suspicion (e.g., Alcock 1998; Maynard Smith 1995; Queller 1995; for a philosopher's perspective, see Sesardic 2005). Pigliucci (2010) does not openly express any political biases; but in any case, his work certainly does not offend prevailing leftist academic opinion, e.g., via glaring misrepresentations of *The Bell Curve* discussed above. This is further seen in his evident sympathy to Gould and Lewontin's deeply flawed scientific theorizing. Whereas, again, the overall opinion of Gould and Lewontin among biologists is overwhelmingly negative, Pigliucci (2010) offers only tepid criticisms of Gould (but not Lewontin) and his attacks on evolutionary psychology are general enough to place him squarely in the non- or anti-adaptationist camp that Gould and Lewontin founded, or at least reinvigorated (see Sesardic [2005, p. 57] for more evidence of Pigliucci's positively slanted view of Lewontin; Sesardic

elsewhere [e.g., p. 166] highlights Pigliucci's basic alignment with Gould and Lewontin's research program). (As a general rule, those working in the philosophy of biology, e.g., Pigliucci, regard Gould and Lewontin more positively than do evolutionary biologists. This is perhaps due to Lewontin's academic relationships with many highly influential philosophers of biology of the twentieth and twenty-first centuries, such as Philip Kitcher, Peter Godfrey-Smith, and Elliott Sober.)

But why does leftism, including Marxism, generate among its adherents hostility to biological explanations of human behavior? The answer seems to be that leftism is typically aimed at social and political change or even revolution, usually for the sake of promoting certain forms of equality and freedom. Biological explanations of human behavior, insofar as they imply that there are limits to human behavioral change that cannot be surmounted without genetic change, threaten the social and political aspirations of leftists (Winegard and Winegard 2017). There are cases in which intellectuals on the left have been quite transparent about their fears that human biobehavioral science will have such implications. For example, in her book, *Testosterone Rex*, Cordelia Fine (2017), a feminist psychologist turned philosopher, although ostensibly taking up the *scientific* project of correcting inaccurate views about human sex differences in behavior, ends up revealing moral-political motivations early on in her effort: "Although scientific claims don't tell us how our society *ought* to be, that being the job of our values, they can give us strong hints as to how to fulfil those values, and what kind of arrangements are feasible. . . [I]f the sexes are essentially different, then equality of opportunity will never lead to equality of outcome" (pp. 20–21; emphasis in the original) (tellingly, she goes on to write that her critical target, an account of the biological bases of human behavioral sex differences that she terms "Testosterone Rex," "can appear undefeatable" [p. 22], a phrasing more at home in the world of ideological combat than of science). Anxiety surrounding the apparent tension between human behavioral biology and leftist political agendas has had the unfortunate effect of motivating deliberate (see Alcock 1998)

perversions and obfuscations of science. One of the more salient cases is Gould's corpus, which is largely an effort to restructure evolutionary theory so as to minimize the role of adaptationist explanation in the life sciences and which was also significantly motivated by Marxist politics. What makes this effort remarkable is its signal failure to produce anything resembling a legitimate alternative to adaptationism. As discussed earlier, there is no real "exaptationist research program," despite Gould and Lewontin's efforts, because non-adaptationist forms of evolutionary theory provide no basis for the development of scientific predictions (Figueroa and Berry 2002).

Taken collectively, these considerations suggest that radical critiques of evolutionary psychology, and the broader revisionist projects in evolutionary biology to which they are connected, are not intended to advance scientific understanding at all. Rather, they are efforts to retard or derail the development of science, for the sake of protecting theoretical models of human behavior that the political left favors. This is the most parsimonious explanation of the fact that Gould and Lewontin and related scholars only attack biosocial theories of human behavior, even as they (1) stress the supposed inability of scientists to understand the relative contribution of genetic, or at least evolutionary, factors to human behavior and behavioral variation (which necessarily leaves the *relative* importance of social factors unclear as well) and (2) uncritically present very poorly supported or discredited sociological hypotheses as superior alternatives to biologically informed theories of human behavior, alternatives which are always convenient for leftist causes. An example of this sort of tendentiousness comes from Lewontin et al. (1984): "Strong performance on IQ tests is simply a reflection of a certain kind of family environment" (p. 94). Years before Lewontin et al. published the book in which the foregoing statement appears, it was already known with great confidence, through behavior genetic studies of twins, that family environment accounts for none or virtually none of the variance in IQ among adults, whereas genetic factors were (and continue to be) found

to account for 70–80% of the variance (Jensen 1969; Plomin and Deary 2015). Jensen (1969) reviewed relevant evidence from twin studies well before the publication of Lewontin et al.'s (1984) book; Lewontin et al.'s (1984) attempt to critique Jensen's analysis reduces largely to attacks on the scientific integrity of Cyril Burt, on whose science Jensen partially relied (see Tredoux 2015 and Sesardic 2005 for defenses of Burt), and efforts to explain away the findings of twin studies that were at odds with and ignorant of the science of their day (see Nyborg 2003), and are still recognized as confused and baseless (see Sesardic 2005). Notably, Lewontin et al. (1984) offer no rigorous support for their environmental determinist view of intelligence differences, and subsequent research has borne out Jensen's estimates of the relative importance of the environmental and genetic variance components of IQ (see Plomin and Deary 2015). The only apparent explanation for such flagrant misrepresentation of the then state of intelligence research is that Lewontin et al. (1984) were writing explicitly for the purpose of advancing a Marxist agenda, and such a program for radical and egalitarian societal change is incompatible with genetically rooted inequality in a trait as socially important as intelligence.

Curiously, to the extent that Gould and Lewontin sought to safeguard leftist agendas from progress in the life sciences through their non- or anti-adaptationist program – and there is ample evidence that Gould especially sought to replace ultimate biological/adaptationist models of behavior with proximate environmentalist ones (Alcock 1998) – it is not clear that they would have succeeded in this effort even if their alternative takes on evolutionary biology had fared well. To take one example, Gould was fond of stressing the possibility that genetic drift might account for a great deal of evolutionary change that was allegedly wrongly attributed to selection. But some feature of an organism that comes about through genetic drift is no less rooted in genetics than a feature that emerges through selective processes. Thus if Gould hoped that explaining away selection and adaptation would

legitimately advantage environmentalist explanations of behavior, this was simply without sense. So, assuming that there was some rationality behind his project, it would seem that he really intended to thwart successful biological theorizing by obscuring the nature of evolution so thoroughly as to render it a muddle of causal processes that could not be disaggregated and comprehended. At worst (for Gould) and if it were successful, this would leave scientists in a sort of agnosticism about the role of evolved factors in human behavior; at best, it would have such scientists focus only on proximate and environmental models of human behavior (Alcock [1998] reaches a similar conclusion about Gould's intentions). The psychometrician Chris Brand (1999) identified the same basic strategy among environmental determinists in the IQ debate, who were (and still are) fond of using it to arrest scientific progress, or at least the recognition of such progress, in the camp of their hereditarian opponents: "Instead of seeing themselves as offering a competing social-environmentalist theory that can handle the data, or some fraction of it, the sceptics [i.e., anti-hereditarians or environmental determinists] simply have nothing to propose of any systematic kind. Instead, their point – or hope – is merely that everything might be so complex and inextricable and fast-changing that science will never grasp it" (p. 775).

The philosopher of science Imre Lakatos (1970) drew a distinction between what he termed "progressive" and "degenerating" research programs. Whereas the former generate novel hypotheses and predictions that enable the development of scientific knowledge, the latter merely offer ever more elaborate justifications of existing theories to guard them against disconfirmation; therefore, degenerating research programs do not produce knowledge, because they do not devise novel hypotheses and predictions and thus fail to advance scientific understanding. It should be patent from the details given above that radical critiques of evolutionary psychology are the products of a degenerating research program (or programs, depending on how one wishes to

carve up the pertinent academic terrain). Radical critics, like the skeptics of IQ hereditarianism characterized by Chris Brand, have no serious alternative to evolutionary psychology. They seek only to convince others that empirically impoverished and theoretically garbled, but leftist-friendly, sociocultural theories of human behavior are adequate (even though these have been shown to fail time and again; see, e.g., Boutwell and Connolly 2017; Figueredo et al. 2007; Woodley and Figueredo 2013), or at minimum to cast irresolvable doubt over biosocial explanations, so that the pure environmental determinist models can (appear to) be spared definitive refutation. Therefore it might be said that the radical opposition to evolutionary psychology is *necessarily* degenerative, because it is not in fact concerned with uncovering the true nature of human behavior. From the beginning, it is structured to reach morally and politically desired answers, or in other words to maintain the apparent (to some) integrity of a preconceived (leftist) worldview. While intrinsic critiques will continue to refine and improve evolutionary psychological science, the anti-scientific character of radical critiques will most likely lead to their eventual and unanimous rubbishing among the relevant academics, especially given that particular moral and political biases never retain intellectual hegemony in the long run.

Convergent Evolution of Dog and Human Social Cognition

Monique A. R. Udell
Oregon State University, Corvallis, USA

Synonyms

Comparative cognition; Human-dog symbiosis

Definition

The evolution of similar socio-cognitive traits in dogs and humans as a product of shared or similar selection pressures.

Introduction

Domestic dogs and humans have shared a close symbiotic relationship for at least 14,000 years (Nobis 1979). Both species entered into this relationship with complex social systems with a much longer evolutionary history. This likely enhanced mutual compatibility during early dog domestication.

While the details surrounding dog domestication remain an area of active debate, there is evidence that the early dogs were free-living scavengers that exploited a new niche – a nutrient source created by concentrated areas of human waste and refuse – that developed alongside stable human communities (Coppinger and Coppinger 2001). The majority of dogs around the world still exist within this niche. However domestic dogs have also become increasingly integrated into human societies and homes, with as many as 80 million pet dogs in the United States alone (APPA 2014). Dogs are also now employed in a wide range of working roles ranging from hunting, livestock management, and athletic partners to police and military aids, search and rescue, therapy, and service animals. Especially within the last several hundred years, these additional roles have increased the amount of intentional

trait selection imposed on dogs by humans. This long-standing symbiotic relationship between humans and domestic dogs, coupled with reported similarities in some socio-cognitive tests, has raised questions about possible convergent evolution of social cognition between these two species.

Support for Possible Dog-Human Convergent Evolution

Many aspects of human social cognition differ in important ways from humans' closest relatives. This is likely due to a combination of evolutionary and lifetime selection pressures. Certain traits such as the tendency to follow other's gestures and gaze, imitation, cultural practice, theory of mind (or the capacity to recognize that others have different knowledge states from our own), and the use of language are often considered hallmarks of human social cognition (Dunbar 2003). Consequently, much attention has been given to scientific pursuits designed to determine if our closest genetic relatives share some or all of these traits.

In the 1990s some of this focus shifted away from our closest relatives toward one of our closet companions, the domestic dog. While there has been a long history of scientific interest in the behavior of the domestic dog, research on human-dog interactions and canine cognition began expanding rapidly after several studies demonstrated that pet dogs' capacity to follow the pointing gestures of humans surpassed that of nonhuman primates (Hare and Tomasello 1999; Miklósi et al. 1998). These studies were quickly followed by more reports of pet dogs' social responsiveness, including sensitivity to human attentional state, emotional state, vocalizations, as well as an increased tendency to look at humans, especially in cooperative contexts (Udell et al. 2010). In 2005 it was proposed that the seemingly humanlike characteristics of pet dog's social cognition might be explained by convergent evolution with humans, based on the belief that chimpanzees and gray wolves did not share

this same sensitivity to human cues (Hare and Tomasello 2005).

Challenges and Other Considerations

The hypothesis that dog domestication resulted in a more humanlike social cognition has more recently been challenged by data demonstrating that many of these socio-cognitive traits are not unique to dogs or even domesticated species (Range and Virányi 2015; Udell et al. 2010). For example, wolves have been shown to excel on human-guided tasks and form functional attachment bonds to human caretakers if hand reared by humans (Udell et al. 2010). It is also now clear that experience, including socialization during early development and with specific human actions, is an important predictor of whether a dog will develop sensitivity to human actions and to what degree. Dogs with minimal human exposure, and those living outside of human homes in animal shelters or research labs, typically do not perform well on human-guided tasks without additional training (Udell et al. 2010).

Despite this, some findings related to differences in the social behavior and cognition of dogs and wolves have remain robust and appear to correspond with known behavioral, biological, and genetic changes associated with domestication. These differences include exaggerated proximity seeking behavior and extended gaze durations toward companions when compared to wild-type ancestors, elevated oxytocin levels as a result when in contact with human companions, and inhibition of independent problem-solving behavior under ambiguous or social conditions (Udell and Brubaker In Press). Many of these changes appear to correspond with developmental delays associated with the domestication syndrome more broadly, including morphological and behavioral neotony and shifts in the critical period for social development (Lord 2013). Coupled with living conditions that often reward, if not mandate, a pet or working dog's dependence on humans into adulthood, this evolutionary, developmental, and experiential relationships likely contribute heavily to the unique socio-

cognitive skills and depth of cross-species attachment reported within these populations.

Conclusions

While the domestic dog's social cognition has likely contributed to their success in human environments, the degree to which their socio-cognitive tendencies are uniquely comparable to adult humans is debatable. It may be more accurate to suggest that given early exposure to human environments, domestic dogs may retain (into adulthood) aspects of social cognition and attachment behavior more similar to the social cognition of human children than would be typical of wild-type species (Udell and Brubaker in press). This is consistent with what is known about the relationship between domestication and developmental delays. More mature aspects of human social cognition shared by dogs also appear to be shared, and in some cases surpassed, by the abilities of wolves (Range and Virányi 2015). Therefore, if convergent evolution contributed to similarities in dog-human social cognition, this may have occurred prior to domestication. However, research in this area is ongoing, and new developments are likely in years to come, especially given the recent vibrancy of research within this field.

Convergent Evolution of Hyena and Primate Social Systems

Kay E. Holekamp
Department of Integrative Biology, Program in Ecology, Evolutionary Biology, and Behavior, Michigan State University, East Lansing, MI, USA

Definition

Societies of distantly related mammals may evolve in parallel fashion, along with the cognitive abilities that mediate social interactions, in widely divergent taxonomic groups.

Introduction

The societies of spotted hyenas (*Crocuta crocuta*) are remarkably similar to those of cercopithecine primates, which are old world monkeys such as baboons and macaques. Spotted hyenas are large mammalian carnivores that occur throughout sub-Saharan Africa. Although spotted hyenas last shared a common ancestor with primates roughly 90 million years ago, convergent evolution has produced the same social structures in these two distantly related mammals, and the same cognitive abilities needed to mediate social behavior. With respect to their size and complexity, the societies of spotted hyenas much more closely resemble those of primates than those of other terrestrial carnivores. Like old world monkeys, spotted hyenas live in permanent complex social groups, called clans (Kruuk 1972), which range in size from 20 to 130 individuals. On the prey-rich plains of eastern Africa, hyena group size does not differ appreciably from that of sympatric baboon troops. Furthermore, like most primates, hyenas within each clan can be ranked in a linear dominance hierarchy based on outcomes of agonistic interactions (Fig. 1). Although cercopithecine primates feed mainly on vegetable matter whereas spotted hyenas feed on carcasses of the herbivores they have killed, in both hyenas and monkeys priority of access to critical food resources varies with the social rank of individuals in the group’s dominance hierarchy (Holekamp et al. 2012).

Convergent Evolution of Social Structure

As in monkey troops, all members of a hyena clan recognize one another as individuals using multiple sensory modalities; they also cooperatively defend a common territory and rear their cubs together (Kruuk 1972). Like cercopithecine primates, spotted hyenas establish enduring relationships with clan-mates that may last many years, often spanning multiple decades. Like baboon troops, hyena clans contain multiple adult males and multiple matriline of adult female kin with offspring, including individuals from several

Convergent Evolution of Hyena and Primate Social Systems, Fig. 1 Dominance rank order of matriline within one cohort of adults present in a single large clan of spotted hyenas. As in a baboon troop, the dominance hierarchy of natal animals contains multiple matrilineal kin groups, shown at left; each matriline is represented by a different color. Squares in genealogies represent males and

circles represent females. Although only adult females are shown among the natal animals in the vertical listing at right, offspring are included in the genealogies shown at left; as in baboons, offspring slot into the hierarchy immediately below their mothers. In contrast to the rank ordering in monkey societies, however, all adult female hyenas and their young outrank all immigrant males

overlapping generations (Fig. 1). Breeding males in both taxa are usually immigrants born elsewhere. As in virtually all cercopithecines, male hyenas disperse voluntarily from their natal groups after puberty, whereas females are usually philopatric. As in many monkeys, relatedness is high within hyena matriline but, on average, clan members are only very distantly related due to high levels of male-mediated gene flow among clans. Thus both monkeys and hyenas interact on a daily basis with both kin and non-kin.

As in female cercopithecine primates, the social ranks of female hyenas in the clan's dominance hierarchy are not correlated with size or fighting ability; instead, power in both monkey and hyena societies resides with the individuals

having the strongest network of allies, and ally network size is highest in the highest-ranking matriline (Smith et al. 2010, 2011; Fig. 1). As they grow up in their natal groups, young spotted hyenas assume ranks in the clan's dominance hierarchy that are isomorphic with those of their mothers. As with young monkeys, young hyenas learn their positions in their clan's dominance hierarchy via a process of "maternal rank inheritance," and non-littermate hyena siblings assume relative ranks that are inversely related to age in a primate-like pattern of "youngest ascendancy" (Horrocks and Hunte 1983; Holekamp et al. 2012). Learning is a critical aspect of rank acquisition in both spotted hyenas and monkeys, and individuals clearly remember outcomes of

earlier encounters with particular group-mates. As in primates, coalitions play an important role in acquisition and maintenance of social rank in spotted hyenas (Horrocks and Hunte 1983; Smith et al. 2010). In both hyenas and cercopithecine primates, members of the same matriline occupy adjacent rank positions in the group's hierarchy, and female dominance relations are extremely stable across contexts and time. However, one interesting difference between hyenas and cercopithecine primates in regard to rank is that adult female hyenas dominate adult males (Kruuk 1972, Fig. 1), whereas male cercopithecines dominate females.

As in cercopithecine primates, all female spotted hyenas breed, but their reproductive success varies with social rank. The mechanisms mediating rank-related variation in reproductive success are remarkably similar between old-world primates and spotted hyenas. In both taxa, dominant females use aggression or displacement to gain better access to key resources. As in various primates, high-ranking female spotted hyenas start breeding at younger ages, produce more surviving offspring per unit time, and enjoy longer lifespans than do their low-ranking counterparts, and these differences have profound long-term fitness consequences (Hofer and East 2003; Holekamp et al. 2012). However, as in female baboons (e.g., Silk et al. 2010), the fitness of female spotted hyenas is strongly affected by sociability as well as by dominance rank. Life span is a major determinant of fitness in spotted hyenas, and highly gregarious females live longer than others. Like monkeys, hyenas can also use social strategies to offset certain costs of low rank. For instance, mid- and low-ranking hyenas who associate most closely with higher-ranking individuals are allowed to feed with them most often at ungulate kills (Smith et al. 2011).

Finally, patterns of intragroup cooperation in spotted hyenas are surprisingly similar to those documented among cercopithecine primates. Spotted hyenas often help both kin and non-kin allies defend their resources against alien hyenas or lions, and by doing so may risk serious injury or death (Kruuk 1972). As in baboons (Silk et al. 2010), female hyenas form long-lasting

affiliative relationships with a subset of other females in their clan, with the strongest bonds occurring among close matrilineal kin (Smith et al. 2011; Holekamp et al. 2012). Thus, as in many primates, hyenas have enduring cooperative relationships that affect survival and reproduction of individual group members.

Clearly, spotted hyenas share many aspects of their social biology with old-world primates, indicating that there has been strongly convergent evolution of their societies. Although some primatologists claim that primate societies are more complex than those of other mammals, the characteristics of hyena societies reviewed here suggest otherwise. The striking similarities in the social lives of monkeys and spotted hyenas have also promoted strongly convergent evolution of their abilities in the domain of social cognition (Holekamp et al. 2015).

Convergent Evolution of Social Cognitive Abilities

Cercopithecine primates possess well-developed cognitive abilities that make them unusually adept at predicting outcomes of behavioral interactions among their group-mates (e.g., Cheney and Seyfarth 1990, 2007). They recognize individual conspecifics based on their voices and faces, discriminate kin from non-kin, and may even be able to recognize paternal kin in the absence of paternal care. Nepotism is common in most primates, and kin also form stronger bonds than do non-kin (e.g., Cheney and Seyfarth 1990; Silk et al. 2010). As they mature, monkeys assume their places in the troop's dominance hierarchy through a protracted process of associative learning during interactions with group-mates (e.g., Cheney and Seyfarth 1990; Horrocks and Hunte 1983). They know that group-mates vary in their value as social partners, and they attempt to repair valuable relationships when those are damaged (e.g., Cheney and Seyfarth 1990, 2007). Monkeys clearly remember outcomes of earlier encounters with particular conspecifics, and they modify their social behavior on the basis of interaction histories (Cheney and Seyfarth 1990, 2007).

Furthermore, they possess knowledge about the social ranks of their group-mates and about the social relationships among their group-mates, and base their decision-making in social situations upon this knowledge. Due to convergent evolution, spotted hyenas share all these capabilities with cercopithecine primates.

Spotted hyenas can recognize individual group-mates using visual, acoustic, or olfactory cues (Kruuk 1972). For example, they can identify individual conspecifics and distinguish kin from non-kin, on the basis of their long-distance “whoop” vocalizations, and whoops also convey information about the caller’s age, sex, and motivational state. Hyenas also have a keen olfactory sense; each clan has a unique scent signature, mediated in part by volatile products of metabolism in the symbiotic microbes inhabiting the hyenas’ scent glands, and hyenas can distinguish scents of their clan-mates from those of hyenas from other clans. Spotted hyenas also use olfactory cues to discriminate sex, reproductive state, and familiarity of conspecifics.

Nepotism is common among spotted hyenas; social bonds are stronger among kin than non-kin (Holekamp et al. 2012; Smith et al. 2010), and individuals direct affiliative behavior most frequently towards kin. Although male hyenas do not participate in parental care, sires can recognize their offspring, and vice versa; this most likely occurs via phenotype matching. Furthermore, full sibling littermates associate more closely and direct more affiliative behavior toward one another, than do half-sibling littermates. When deciding whether or not to join on-going fights, female spotted hyenas support close kin most often, and the density of cooperation networks increases with genetic relatedness; nevertheless, as in primates, kinship fails to protect female hyenas from coalitionary attacks (Smith et al. 2010). As in monkeys, hyenas are more likely to attack the relatives of their opponents after a fight than during a matched control period, and after a fight they are more likely to attack relatives of their opponents than to attack other lower-ranking animals unrelated to their opponents.

As in monkeys, spotted hyenas recognize that their social partners vary in relative value to them and that they make adaptive choices regarding

with which clan-mates to associate. Although interactions between male and female spotted hyenas are almost exclusively initiated and maintained by males, females often mate with their closest male associates. Males prefer to associate most closely with the highest-ranking females, whose offspring survive far better than do offspring of low-ranked females, so this preference by males appears highly adaptive, although it is not known how males discriminate female rank. Adult hyenas of both sexes prefer to associate with non-kin holding ranks similar to their own. Furthermore, patterns of greeting behavior in spotted hyenas follow primate patterns of social grooming in which individuals prefer to spend time with, and direct affiliative behavior towards, high-ranking non-kin (Cheney and Seyfarth 1990; Smith et al. 2011).

Spotted hyenas use unsolicited appeasement and greeting behaviors to reconcile their fights. As is also true in many primates, victims in hyena fights are significantly more likely to reconcile than are aggressors. Furthermore, spotted hyenas can recognize third-party relationships among their clan-mates. Third-party, relationships involve interactions and relationships in which the observer is not directly involved. Like monkeys, hyenas can recognize third-party relationships based on either social rank or kinship, and they use this knowledge in adaptive decision-making. Hyenas clearly make flexible decisions regarding whether or not to cooperate or compete with conspecifics, modifying their behavior based on multiple types of information about their immediate social and ecological environments (Smith et al. 2010).

Conclusion

It is clear that convergent evolution has produced remarkable similarities between old-world primates and spotted hyenas, not only with respect to their social lives per se but also to the cognitive abilities that allow animals in both taxonomic groups to successfully navigate their large, complex societies. Although some social cognitive abilities known in primates have not yet been explored in spotted hyenas, the hyenas’ behavior

indicates that they can otherwise solve all the same social problems that primates can solve. Thus it appears that convergent evolution of social complexity promotes convergent evolution of social cognition.

Convergent Evolution of Cognition

Definition

When two or more distantly related species evolve similar cognitive adaptations in response to comparable environmental challenges.

Introduction

Convergent evolution occurs when two distantly related species evolve a similar trait as a result of experiencing similar environmental conditions. As cognitive traits are equally subject to evolutionary pressures as other biological traits, it may seem intuitive that natural selection would have produced comparable cognitive abilities in a range of species that occupy similar niches. However, the focus on convergent evolution in cognitive research is a relatively recent phenomenon. Instead, studies of animal intelligence have long tended to emphasize the importance of phylogenetic continuity – that is, cognitive similarities stemming from common descent – particularly in the context of understanding the evolutionary origins of human intelligence. Our closest relatives, extant nonhuman primates were long

assumed to be the most logical species group for investigating the evolutionary origins of intelligence (e.g., Byrne 1995). Only more recently has it become apparent that species from dissimilar taxonomic groups, such as corvids and cetaceans, share important aspects of intelligent behavior with primates (Emery and Clayton 2004; Marino 2002). Moreover, almost every cognitive trait present in primates has also been found in taxa ranging from fish to insects (Bshary et al. 2002; Chittka et al. 2012). This entry outlines what is known about the evolutionary pressures that contribute to convergent intelligent behaviors, while highlighting examples of species and behaviors that do not fit current evolutionary predictions. Despite having made progress on evolutionary theory surrounding intelligence, such anomalies illustrate how much more the field has to learn about the conditions that favor intelligence.

What Is Intelligence?

Animals routinely encounter uncertainty in their environments. Fluctuations in resources, in abiotic conditions, or in the behavior of others, can grant a fitness advantage to animals that make adaptive decisions in the face of uncertainty (Dall et al. 2005). From a broad perspective, intelligence involves the neuronally controlled means by which animals can make such adaptive decisions. While there is no consensus on precisely what constitutes intelligence, it is arguably best envisaged as an umbrella term for a range of cognitive abilities that allow animals to employ flexible behavior and extract generalizable rules, instead of having to rely on reflexive stimulus-response reactions or rote learning when conditions change (Byrne 1995; Mackintosh 1988). Under such broad terms, many types of cognitive traits can contribute to intelligence, and how this capacity manifests itself depends on the species and the type of environmental uncertainty they encounter. Evolution could favor specific cognitive adaptations to cope with a set of well-defined ecological challenges (Shettleworth 2010) or could favor more general abilities that could be

used across a variety of contexts, such as associative learning (Heyes 2012). Specific selection for convergent cognitive specializations can be seen, for example, in the enlarged hippocampus and greater spatial memory of food-caching birds (Olson et al. 1995) and scatter-hoarding rodents when compared to closely related, non-food-storing species (Barkley and Jacobs 2007). Meanwhile domain-general forms of intelligence, in which performance in a trait is correlated across multiple contexts, may stem from a variety of evolutionary pressures that are harder to pinpoint. The types of evolutionary questions that can be answered when comparing species' intelligence will be determined by whether investigators measure specific or general forms of intelligence.

How to Measure Intelligence

Since all cognitive traits stem from the brain, variation in brain morphology has clear evolutionary implications for intelligence. The brain is metabolically expensive, and neural tissue growth is evolutionarily conservative, at least in mammals (Finlay et al. 2001). Therefore evolving larger brains or brain regions should give species an advantage that warrants the increased metabolic costs of such structures (Byrne 1995; Herculano-Houzel 2011). Accordingly, greater absolute brain size and relative brain-to-body size have been found to correlate with cognitive ability within species groups (Deaner et al. 2007; Ratcliffe et al. 2006). A common alternative measurement involves comparing the relative size of brain regions that are thought to be linked with intelligent behavior, such as the mammalian isocortex and the avian hyperstratum ventrale (Lefebvre et al. 2004). In contrast to size-related assessments, it has been suggested that comparing the number of neurons within the brain or a brain region of interest better measures the computational power of the brain. This approach has yielded striking examples of convergent evolution in brain morphology. For instance, certain bird species, such as corvids and parrots, have a similar or greater number of neurons in their forebrains than primates have, despite their brain structures

being smaller in size. Therefore these birds may have been able to increase their cognitive capacity by packing a greater number of neurons in their forebrain instead of increasing these brain structures in size like primates did (Olkowicz et al. 2016).

While each of these brain measures are important for understanding the evolution of intelligence, none of them explicitly demonstrate what the brain does with any extra computing power it may have. Without a clear link to the behaviors that enhancements in brain morphology facilitate, it is difficult to connect changes in the brain to impacts on fitness and the evolutionary pressures that favor growth in the size or complexity of neural tissue. Therefore, tests of cognitive ability are a necessary component of comparing intelligence across species.

Since cognition occurs internally, intelligence cannot be assumed to underlie any given behavior without experiments to infer the cognitive mechanisms underlying the behavior. No single cognitive test can measure intelligence as a whole. Instead there are two different ways of assessing intelligence that differ depending on whether researchers focus on understanding cognitive specializations or quantifying domain-general intelligence. Studying adaptive specializations requires hypotheses about which evolutionary pressures would favor a specific cognitive domain, such as spatial memory, and then designing experiments to test that ability. For example, both salmon and sea turtles must navigate long distances in the open ocean in order to return to specific spawning or nesting locations. When tested on their homing abilities, both rely on the geomagnetic field to find their way, suggesting that this uncommon ability is a result of similar navigational challenges (Lohmann et al. 2008). Conversely, researching domain-general cognitive abilities involves conducting a battery of tests that capture a similar underlying trait (such as associative learning or discrimination ability) across multiple contexts. When conducted comparatively, this approach helps determine how much selection in one context, such as cooperative foraging, influences abilities in other contexts, such as spatial discrimination (e.g., Gingsins and Bshary 2016).

Even with a specific test or set of tests in mind, researches face challenges when comparing intelligence across species. Potential morphological or motivational differences between species can confound comparisons. For example, in tests of inferential reasoning abilities, elephants fail to choose the correct option when stimuli are comprised of the traditional auditory cues that are often used for primates, but succeed if the cues are olfactory in nature (Plotnik et al. 2014). Since experiments that are ecologically relevant are most likely to provide evidence for cognitive capacities (e.g., Gingsins and Bshary 2016), tests often need to be fine-tuned when deployed on a new species.

Evolutionary Pressures Favoring Intelligence

Food Availability

If intelligence serves to reduce uncertainty about an aspect of the environment, then increased intelligence should be favored by selection in environments that contain increased uncertainty. One source of uncertainty that all animals must face is in finding food. The reliability and distribution of food differs, which has been suggested to drive specific cognitive mechanisms depending on the type and amount of variability animals must overcome in finding their food. Foragers that must find patchily distributed or moving prey might gain fitness advantages for being behaviorally flexible, planning ahead, or remembering the location and value of particular resources. For example, animals that must remember the location of a specific food source in relation to how it changes over time, such as those that cache perishable food or forage on nonsynchronously ripening fruit, may do better if they are able to integrate such memories in an episodic way. Such theories have been used to explain episodic memory in Western scrub jays that cache food (Emery and Clayton 2004) and the ability of mangabey monkeys to account for the weather since they last visited fruiting trees (Janmaat et al. 2006). Prey distributions may not only influence selection for memory but also bias the way in which animals learn about their current environments. For example, nectar-feeding birds

and bees both face the challenge of maximizing foraging intake when feeding on rapidly depleting nectar sources, and thus both employ a “win-shift” cognitive strategy (i.e., learning to avoid rewarding places) which allows them to avoid visiting empty flowers (Demas and Brown 1995; Sulikowski and Burke 2007).

Seasonality and Habitat Heterogeneity

Abiotic aspects of the environment, such as the harshness of seasonal change, can also select for different cognitive capacities depending on whether an animal endures the changes or migrates to more benign climates. For instance, resident species typically demonstrate greater numbers of novel foraging behaviors, a trait sometimes considered to represent a species’ behavioral flexibility or innovation propensity (Sol et al. 2005). Conversely, migratory bird species commonly show increased long-term spatial memory capacities when compared to residents, enabling them to remember advantageous stop-over sites. Such abilities may, however, come at a cost, as they tend to be less exploratory at those sites and have smaller brains, presumably to help reduce energy consumption (Mettke-Hofmann 2016).

Other habitat variability that animals encounter, such as how quickly habitats change over short distances, can also influence evolutionary pressures on cognitive behaviors. The amount of habitat heterogeneity that species experience has been suggested to influence differences in spatial navigation and route learning, such that populations that occupy more stable environments such as lakes more readily rely on landmarks in navigating. Meanwhile, populations occurring in more variable habitats, such as rivers, appear to learn routes more quickly and rely more on egocentric navigation (Sheenaja and Thomas 2011).

The influence of the abiotic environment and habitat variability does not occur in isolation of other evolutionary pressures. For instance, spatial environmental variability coupled with group living would select for behavioral flexibility and social learning as groups move and adjust to varying environments (Rendell and Whitehead 2001).

This theory would predict that species with low travel costs and reduced territorial restrictions would particularly encounter these types of pressures (Knight 2001). Therefore, assessing the influence of the environment on the evolution of intelligence also requires an understanding of how animals interact with and within that environment.

Sociality

The social environment can generate substantial levels of uncertainty depending on how individuals interact with conspecifics. For instance, social animals may face challenges in responding to others, such as needing to recognize individuals, track relationships, deceive conspecifics, or avoid being deceived themselves. Moreover, individuals may also benefit from cognitive strategies to maximize the fitness gains obtained through learning from or cooperating with conspecifics. Abilities that allow animals to tackle these challenges or take advantage of these opportunities fit into the category of social intelligence or social cognition. Such abilities include being able to follow the gaze of others to determine where their attention lies, to imitate other’s behavior, and to understand what others may be thinking (Theory of Mind). According to the “Social Intelligence Hypothesis,” or the “Social Brain Hypothesis,” social environments that contain more of these challenges and opportunities select for such cognitive abilities (Humphrey 1976). For example, species such as primates, hyenas, and ravens all live in dynamic social groups that contain dominance hierarchies and would therefore be subject to similar evolutionary pressures. Accordingly, each of these species are able to understand relationships between two outside individuals (third party relationships) and to infer what those relationships mean for oneself (Engh et al. 2005; Massen et al. 2014). Moreover, the challenges of the social environment are not restricted to terrestrial animals, as different species of bony fishes display many behaviors indicative of social intelligence in primates, such as cooperative hunting, individual recognition, and social learning, arguably because they face similar social dilemmas (Bshary et al. 2002).

Despite the existence of examples where social systems seem to predict certain cognitive abilities, the “Social Intelligence Hypothesis” is still under scrutiny. Aspects of social intelligence, such as social learning, have been documented in solitary species such as a tortoise (Wilkinson et al. 2010). Additionally the generality of evolutionary pressures in the social domain is also contentious when subject to broader comparative analyses. For example, although the enlarged mushroom bodies (higher brain structures) of social insects have been suggested to stem from pressures of their colonial living, many other nonsocial insects share neuronal structures of a similar size or have similar learning abilities (Roth 2015). Moreover, phylogenetic analyses show that evolutionary pressures associated with a parasitoid lifestyle, such as host-finding behavior and central place foraging, better explain these brain morphology changes (Farris and Schulmeister 2010). Such anomalies and the current variation in intelligence seen across species with similar social structures indicate that social systems are not the only evolutionary driver of intelligent behavior, even in the social domain.

Life History Traits

Life history traits help determine whether animals would benefit from enhanced cognitive capacities, because they dictate how animals interact with their environments. An animal’s life span, and their length of juvenile development, for example, have both been implicated as having importance for intelligence. A long life-span coupled with menopause has been suggested to favor social learning, long-term memories, and group-specific or cultural behavior in orcas, short-finned pilot whales, and humans (Brent et al. 2015). A shorter lifespan, in contrast, could help explain why some species may not express traits predicted by their foraging ecology. For example, despite suggestions that nomadic species may experience convergent selection for long-term spatial memory to help remember foraging sites, such a memory would not be useful for species of seed-eating birds that do not live long enough to experience a full seed cycle (Mettke-Hofmann 2016). The duration of development during the lifespan is

also important. Prolonged infant development is necessary to support the growth of a large brain and extended period of learning. Therefore lengthy gestation and juvenile dependence (i.e., the lifestyle of *k*-selected species) often characterizes species with larger brains and those assumed to be more intelligent (Rushton 2004).

Convergence Across Multiple Cognitive Domains

Specific cognitive adaptations are much easier to explain in relation to the pressures of the ecological and social environment than examples of domain-general intelligence are. Although some species are considered to be “jacks of all trades” in their intelligence, they share many of the same environmental pressures which are often implied in influencing specific cognitive traits. For example, primates, odontocete cetaceans (toothed whales), parrots, and corvids all live in complex social groups, forage on spatially or temporally variable foods, have relatively larger, more complex or more neuronally dense brains, and have longer periods of development in comparison to closely related species. Moreover, all of these species show impressive performance in various cognitive tests in the physical and social domains (Emery and Clayton 2004; Marino 2002). Identifying what combination of evolutionary pressures triggered similar levels of intelligence in corvids, cetaceans, and primates would be useful in understanding what contributed to the evolution of human cognitive abilities. However, it is not yet clear to what extent selection in one domain – social intelligence, for example – influences cognitive flexibility in other domains, although social intelligence has been suggested to foster other aspects of intelligence (Humphrey 1976). Therefore, it is unknown whether a certain combination of ecological factors promotes domain-general intelligence and the lack of others facilitates modular selection for a specific cognitive trait.

The identification of broad convergence in intelligence across several taxa is useful for supporting the argument that intelligence may have evolved independently in multiple clades.

However, despite the discovery of these convergent traits across primates, cetaceans, and large-brained birds, the evolutionary explanations for their intelligence has been a largely post hoc process. Regardless of whether resource, climatic, or social uncertainty is under scrutiny, phylogenetically broad investigations are necessary for verifying hypotheses about the evolutionary mechanisms that favor intelligence (MacLean et al. 2012). Meanwhile, evolutionary theory has yet to catch up with the growing body of examples where cognitive traits appear in unlikely species. Incredible examples of intelligent behaviors in species with smaller brains and less “complex” social systems and environments prove there is much more to learn about the drivers of intelligent behavior. Therefore, investigations have yet to tease apart enough evolutionary mechanisms or study intelligence across enough species to fully understand the ecological drivers of intelligent behavior.

Conclusion

The growing evidence for convergent intelligence across diverse taxa highlights the importance of cognitive research in nonprimate species. Undue focus on phylogenetic continuity – concentrating research on the cognitive abilities of our primate relatives – may limit our understanding of human cognitive evolution when lesser related taxa may serve as better models for human traits. For example, human language learning arguably shares greater structural and genetic similarities with birdsong than with communication in apes (Berwick et al. 2011). In addition to understanding our own evolution, a convergent approach to intelligence will help uncover the common environmental drivers of intelligence across the animal kingdom. As the field continues to progress, the use of phylogenetic analyses will allow us to better discriminate convergence versus cognitive similarity due to common descent. Such an approach will likely reveal other evolutionary influences on intelligence that have not yet been considered.

 Evolution of intelligence

Definition

Convergent evolution describes the analogous (as opposed to homologous) acquisition of similar traits in phylogenetically diverse species facing similar selection pressures. Corvids and primates are often observed to exhibit highly intelligent behavior (with intelligence typically operationalized in this context as those behaviors that indicate the presence of advanced capacities once thought unique to humans or cognitive capacities which surpass those of humans). This led Emery and Clayton (2004) to identify primates and corvids as a case of convergent evolution of intelligence, citing the two groups' capacity for causal reasoning, cognitive flexibility, imagination, and prospection as the key ingredients of a shared cognitive toolkit.

Introduction

Primates and corvids comprise some of the most enigmatic study species in the field of comparative cognition. These two groups have produced some of the strongest claims of advanced intelligence among non-human animals. Wolfgang Köhler's *The Mentality of Apes* (1925) argued for a level of intelligence in apes that was primitive relative to that seen in humans but nevertheless sufficiently advanced as to justify the term *intelligent*, an adjective not afforded to any other non-human animal at the time. Nearly 100 hundred years later, Emery and Clayton (2004) published *The Mentality of Crows: Convergent Evolution of Intelligence in Corvids and Apes*, a clear reference to Köhler's seminal work. They observed the large brains (relative to body size) of both groups and argued that the cognitive feats observed in corvids were comparable to those previously celebrated in apes as indicative of advanced intelligence.

What Is Advanced Intelligence?

What constitutes advanced intelligence is a controversial and complex issue (Sulikowski and Burke 2015). Episodic memory, theory of mind, planning, and tool manufacture have all been nominated as feats of advanced intelligence. It is no coincidence that these same abilities are also those that have been indicated (at one point in time) as uniquely human traits. Reports of such advanced cognitive feats in non-human animals (such as the examples cited below) are thus frequently framed as breaking down the discontinuities between abilities (once) thought to be uniquely human and the cognitive abilities of animals more broadly. This anthropocentric perspective of what constitutes advanced intelligence derives from the study of intelligence in primates (described below).

When they first suggested that corvids and apes constituted a case of convergent evolution of intelligence, Emery and Clayton (2004) highlighted examples of corvid cognition from these categories to demonstrate that corvids

exhibited cognitive feats comparable to those seen in apes. They also referred to examples of transitive inference (being able to conclude that A is larger than C, based on knowledge that A is larger than B and B is larger than C) and the extensive spatial memory required to support cache recovery. They argued that four “cognitive tools,” present in both apes and corvids, were necessary and sufficient to support the evolution and development of such complex cognition:

- *Causal reasoning* (this includes reasoning about the physical causes of object-object interaction outcomes, such as occurs during tool use, and also to reasoning about the intentions and motivations of others, necessitating an attribution of agency to others)
- *Flexibility* (the ability to act on information flexibly by generalizing rules learned in one scenario to a novel circumstance or object)
- *Imagination* (the capacity to mentally perceive objects and stimuli that are not currently available to the senses, it would permit contemplation of problems not immediately present and may also support functions like cognitive maps, which require an integrated knowledge of disparate locations which are never simultaneously present)
- *Prospection* (somewhat related to imagination and potentially arising out of it, prospection describes the specific simulation of future events, permitting an individual to act purposefully in accord with future, rather than current, needs and motivations)

Therefore, intelligence in this instance is most appropriately operationalized as the cognitive feats (episodic memory, theory of mind, planning, tool manufacture, transitive inference) that provide evidence of Emery and Clayton’s cognitive tools (causal reasoning, flexibility, imagination, and prospection).

Intelligence in Primates

The study of intelligence in primates has unavoidably anthropocentric roots. Much research on the

cognitive capacities of primates focuses on the comparison between what humans do and what primates can achieve. Against the backdrop of an early twentieth-century presumption of a unique and superior human intellect that was qualitatively unlike that seen in any non-human animal, Koehler’s (1925) work was the first to suggest that another animal, the chimpanzee, may possess a mind capable of the flexibility, creativity, and insight (that was) intuitively recognized as intelligent (albeit not necessarily to the extent seen in man). Much latter-half twentieth-century primate cognition research was guided by a tacit agenda to deconstruct the notion of human uniqueness by closing the cognitive gap between humans and great apes (discussed in Povinelli and Bering (2002)). This was achieved via demonstrations in chimpanzees (and other primates), of cognitive abilities previously presumed to be unique to humans, including theory of mind (the capacity to appreciate that other individuals experience their own perceptions and goals that are independent of your own, reviewed by Call and Tomasello (2008)) and causal reasoning about the physical properties of objects (primarily as pertaining to tool use, reviewed by Call (2010)).

Intelligence in Corvids

Studies of corvid cognition rose to prominence much later in the twentieth century. They appeared against a backdrop of theoretical focus on ecologically adaptive specializations of cognition. Not anthropocentrically motivated, hypotheses were derived and tested based on the selection pressures species were presumed to face. In corvids, initial investigations focused on cognitive adaptations that may have arisen to support foraging. Clark’s nutcrackers recover tens of thousands of seeds, months after caching (necessitating exceptional spatial memory), and New Caledonian crows manufacture specialized hook twig tools and stepped-cut leaf tools to retrieve prey from holes and crevices, implying a causal understanding of the physical effects of the tools (reviewed in Taylor (2014)).

Observations of tool manufacture and use, in particular, invited comparisons between primate

and corvid intelligence (Emery and Clayton 2004; Lefebvre et al. 2004). This motivated further investigations of corvid cognition, focused on demonstrating the nominally intelligent behaviors to date observed only in humans and non-human primates. Subsequent evidence of episodic memory (termed episodic-like memory when observed in non-human animals, since episodic memory itself is a term reserved for human cognition and implies a subjective experience not necessarily observable in non-human animals, reviewed in Salwiczek et al. (2010)), planning (Raby et al. 2007), and theory of mind (reviewed in Taylor (2014)) emerged.

Selection Pressures Leading to Advanced Intelligence in Primates and Corvids

Two broad theories have been put forward to account for the advanced intelligence reported in apes and corvids. The first identifies ecological selection pressures (especially those derived from tool use and manufacture to support innovative foraging behaviors) as the primary drivers behind both larger brains and advanced intelligence (Lefebvre et al. 2004). Within both primates and birds (including but not restricted to corvids), innovative foraging behaviors predict larger brains (especially areas in the forebrain associated with higher-order integration of information) and greater propensity for tool use (Lefebvre et al. 2004). The need to innovate new foraging behavior and to create novel tools could create selection pressure for all four of Emery and Clayton's (2004) cognitive tools to emerge. Flexibility of behavior and prospection (foreseeing the consequences of novel actions) would both promote innovation. Causal reasoning (about the interactions between physical objects) and imagination (to support the insight required to use or fashion novel objects into tools) were argued by Clayton and Emery to be critical to the evolution of tool manufacture and use. Relationships between innovation, brain size, and tool use within other (non-corvid) avian clades suggest that the potential convergent evolution Emery and Clayton

described between corvids and primates may extend to other larger-brained and innovative avian species (including parrots and woodpeckers).

The second theory, known as the social intelligence hypothesis, identifies selection pressures derived from complex social interactions as the key driving force (Holekamp 2007). While social complexity predicts brain size and innovation well in primates, the same is not true for corvids (or birds more generally; Holekamp 2007). As such the applicability of the social intelligence hypothesis to corvids may be limited. Observations of hyenas, who live in complex hierarchically structured social systems, have relatively larger brains than other less socially complex carnivores, and use transitive inference to deduce social ranks of conspecifics, suggest that, within mammals, the social intelligence hypothesis may apply outside primates as well (Holekamp 2007).

These theories ought not to be considered as necessarily mutually exclusive. It is possible, even likely, that selection pressures derived from multiple sources have acted on the brains and cognition of both crows and primates to convergently produce advanced intelligence in these groups. Social complexity may have played a less prominent role in brain enlargement in corvids than in primates; corvids (western scrub jays) nevertheless exhibit evidence of advanced social cognition, in the form of theory of mind (reviewed in Taylor (2014)). As such, the relative contribution of selection pressures derived from social and nonsocial complexity may differ between primates and corvids, but the resulting advanced intelligence manifests comparable ways.

Conclusion

Claims of convergent evolution of intelligence in corvids and primates rest primarily on demonstrations of cognitive feats in both groups that meet intuitive (and somewhat traditional and anthropocentric) notions of advanced intelligence. These include demonstrations of planning, theory of

mind, tool manufacture and use, and episodic memory – all skills once considered unique to humans. Emery and Clayton (2004) proposed that these skills are supported by four cognitive tools (causal reasoning, flexibility, imagination, and prospection), which evolved convergently in corvids and primates. Selection pressures that may have led to these tools include those derived from innovative foraging behavior (especially that involving tools) and from the cognitive complexities involved in navigating social interactions within a large group of conspecifics. Broader comparisons, across other avian and mammalian groups and species, lend support to both possibilities and suggest that the convergent evolution of intelligence observed in corvids and apes may extend to other large-brained, innovative, and social groups of species.

Definition

Cooperation is the performance of a behavior by one individual that provides a benefit to another individual – thereby increasing the recipient's probability of survival or reproduction – and is selected for due to the actor receiving a benefit from the behavior's recipient. In fish, cooperative behavior has been observed in a variety of contexts – including group foraging, cooperative breeding, and anti-predator behaviors – and is maintained by a number of evolutionary mechanisms.

Introduction

The paradox of cooperation has proven to be one of the most enduring questions within evolutionary biology – that is, how can natural selection favor behaviors that may incur costs upon the performer while enhancing the relative survival and reproduction of another individual. An

enormous body of theoretical work has built up over the years proposing a variety of answers regarding both the evolutionary function of cooperation and the proximate mechanisms that maintain or promote it (e.g., Hamilton 1964; Trivers 1971; Axelrod and Hamilton 1981; Noë and Hammerstein 1994; Connor 1995; Ohtsuki et al. 2006; Clutton-Brock 2009; Kingma et al. 2014).

Over the past few decades, fish have become valuable model organisms for the study of cooperation within nonhuman animals due to several reasons. A vast diversity of social systems, morphologies, and life histories can be found within fish (Magnhagen et al. 2008) and many species have been shown to possess impressive cognitive abilities (Brown et al. 2011). Furthermore, fish species often lend themselves well to observation and experimental manipulation under both laboratory and field conditions (see examples within Brown et al. 2011).

Here, representative examples of cooperation among fish will be discussed in terms of the evolutionary mechanisms thought to maintain them. Following Clutton-Brock (2009), these mechanisms include: (1) kin selection, (2) reciprocity, (3) mutualism, and (4) manipulation. In each case, the evolutionary mechanism will be introduced and then relevant examples among fish will be presented. These evolutionary mechanisms are not mutually exclusive; frequently, more than one may help to explain the maintenance of cooperation within a given species or behavioral context. Nevertheless, the above categorization presents a useful framework that highlights relevant mechanistic distinctions while remaining broad enough to avoid over-emphasizing semantics.

Kin Selection

The concept of an individual's inclusive fitness is critical to understanding the evolution of cooperation between related individuals (Hamilton 1964). Inclusive fitness partitions an individual's fitness – i.e., its genetic contribution to future generations – into direct and indirect sources. Direct fitness benefits are gained as a result of an

individual's own reproductive success, while indirect fitness benefits result from assisting non-descendant relatives who propagate genes identical by descent to the actor's own. Hamilton's rule proposes that cooperation will be selected for when $rB - C > 0$, where r is the coefficient of relatedness between the actor and the behavior's recipient(s), B is the benefit to the behavior's recipient(s), and C is the cost to the actor (Hamilton 1964). If a behavior involves some cost to the actor and it is directed at individuals beyond the actor itself, then the behavior must benefit an actor's blood relatives (who share some proportion of the actor's genes) for it to be favored by natural selection. For this reason, this evolutionary mechanism is known as kin selection.

For kin selection to operate, individuals must be able to differentially allocate assistance towards kin over nonkin. Kin recognition has been documented in a number of fish species, including Atlantic salmon (*Salmo salar*) and rainbow trout (*Oncorhynchus mykiss*) (Brown and Brown 1992). In both of these species, individuals display reduced aggression and greater levels of tolerance towards kin relative to nonkin, as well as establish smaller territories when their territories border those belonging to kin (Brown and Brown 1993). These cooperative individuals recoup the costs of increased competition through the indirect fitness benefits gained by helping their kin to survive and reproduce.

When animals live in stable groups with related individuals, kin selection can promote cooperative behavior between group members. Such stable groups often occur within cooperatively breeding species. Cooperative breeding is when subordinate individuals forgo reproductive opportunities and help to raise offspring of dominant breeders (Wong and Balshine 2011; Kingma et al. 2014). Within fish, the best studied cooperative breeder is the Lake Tanganyikan cichlid, *Neolamprologus pulcher* (Wong and Balshine 2011). Groups of *N. pulcher* defend small territories containing rocky terrain that provides shelters and breeding sites. On a territory, there is a pair of dominant breeders and anywhere from zero to 20 subordinate helpers (Fig. 1). Helping

Cooperation Among Fishes, Fig. 1 The social organization of a cooperatively breeding group of *Neolamprologus pulcher*. The pair of dominant breeders tends to be the largest individuals in a group. Subordinate helpers are arranged in a size-based dominance hierarchy below the breeders, where larger helpers are dominant over smaller helpers. Relatedness to the breeder pair, r , is on average higher in smaller helpers compared to larger ones (Reprinted with permission from John Wiley & Sons, Inc. © 2011)

in this species involves: (1) territorial defense against predatory fish, conspecific intruders, and egg predators, (2) territorial maintenance, such as excavating shelters, and (3) egg care (Wong and Balshine 2011).

Helping in *N. pulcher* is a complicated affair, where the costs and benefits of cooperative behaviors vary based on sex, body size and condition, relatedness, and opportunities for dispersal to nearby territories (reviewed in Wong and Balshine 2011). When helpers are related to breeders, kin selection may promote helping behavior by providing indirect fitness benefits to the helper. In *N. pulcher*, smaller, younger helpers are more likely to be related to the breeding individuals (Fig. 1; Dierkes et al. 2005). When subordinates were experimentally removed from their group – thus preventing them from helping – smaller helpers remaining with the group compensated for this absence by increasing their helping efforts, while the efforts of larger helpers remained unchanged (Brouwer et al. 2005). These results are consistent with the hypothesis that smaller subordinates are more likely to assist in caring for the breeders' offspring as a result of gaining indirect fitness benefits from facilitating the reproductive efforts of kin.

Reciprocity

While cooperation between related individuals can be understood in terms of inclusive fitness benefits, cooperation between unrelated individuals poses more of an evolutionary conundrum. One proposed solution which has received a great deal of theoretical and empirical attention over the past several decades has been reciprocity (Trivers 1971; Axelrod and Hamilton 1981; Clutton-Brock 2009). Direct reciprocity – Trivers’ (1971) “reciprocal altruism” – models cooperation between unrelated individuals as an exchange of assistance. Individual A incurs a cost to itself in order to provide a benefit to individual B with the expectation that B will return the favor in the future by providing some benefit to A that outweighs the initial cost. However, reciprocity is not without risks, as the time lag between providing assistance and receiving benefits in return can be exploited by cheaters who benefit from receiving help but do not pay the costs to reciprocate the favor.

The evolutionary dynamics of direct reciprocity resembles the game-theoretic model known as the Prisoner’s Dilemma (Fig. 2). In this model, two players decide either to cooperate with the other player or to cheat via defection. This decision is made by each player without knowledge of

what their partner will choose. Mutual cooperation provides a greater payoff to both players than mutual defection. However, the greatest payoff occurs for a player if they defect when their partner chooses to cooperate, while the cooperator in this scenario receives the worst payoff. If partners play only one round of the game, the only evolutionarily stable solution is for both players to defect in order to avoid paying the costs associated with being cheated. However, in an iterated Prisoner’s Dilemma, in which players play several rounds of the game together, a number of cooperative strategies can emerge (Axelrod and Hamilton 1981).

Tit-for-tat (TFT) is the most well-known solution to the iterated Prisoner’s Dilemma (Axelrod and Hamilton 1981). The TFT strategy is to cooperate on the first round of the game and to copy your partner’s last move in subsequent rounds. In game-theoretic terminology, TFT is “nice” in that it starts out being cooperative, “retaliatory” in that it will defect in response to being cheated, and “forgiving” in that it will resume cooperation if its partner does. This combination of factors allows TFT to potentially reap the benefits of mutual cooperation, while avoiding unbroken strings of being cheated.

Several authors (e.g., Milinski 1987; Dugatkin 1991) have interpreted the dynamics of joint predator inspection in fish as matching those of an iterated Prisoner’s Dilemma (Fig. 2). Predator inspection occurs when one or more fish leave the safety of the shoal and approach a potential predator in order to assess the level of threat it represents. When two or more individuals engage simultaneously in this behavior, it can be viewed as an act of cooperation (Milinski 1987; Dugatkin 1991; Croft et al. 2006). Two individuals inspecting a predator together both receive the benefits of inspection – such as gathering information about the likelihood of an attack – while sharing the potential costs by decreasing the probability that any one inspector will be pursued by the predator. However, individuals that do not inspect a predator – or those that hang back during inspection and continuously allow their partner to take the dangerous lead position – are able to gain information from remotely observing inspection

		Player 2	
		Cooperate	Defect
Player 1	Cooperate	R = 6 Benefit of mutual cooperation	S = 0 Cost of being cheated
	Defect	T = 9 Temptation to cheat	P = 3 Cost of mutual defection

Cooperation Among Fishes, Fig. 2 The payoff matrix for the Prisoner’s Dilemma from the perspective of Player 1. To satisfy the criteria of the Prisoner’s Dilemma, $T > R > P > S$. Mutual cooperation is more beneficial than mutual defection. However, the best payoff is obtained if Player 1 defects – i.e., cheats – in response to Player 2 cooperating, while the worst payoff is for Player 1 to cooperate when Player 2 defects

bouts. This allows for potential defection by allowing one's partner to bear the costs of inspection, while still benefiting from the information gained through their efforts. If no individual inspects, no information can be gained about the potential predator.

During joint inspection events, three-spined sticklebacks (*Gasterosteus aculeatus*) (Milinski 1987) and Trinidadian guppies (*Poecilia reticulata*) (Dugatkin 1991) adopt behavioral strategies that may represent a form of TFT reciprocity. When presented with a potential predator, Dugatkin (1991) found that pairs of guppies initiated inspection events at similar times to one another, lead fish within an inspecting pair were more likely to turn back from the predator than the lagging individual, and after retreating, these former leaders were more likely to wait for their partner to advance before once more advancing themselves. Dugatkin (1991) interpreted these patterns as representing the key qualities of the TFT strategy: "niceness", "retaliation", and "forgiveness," respectively.

Reciprocity is more likely to evolve if cooperators are able to associate preferentially with other cooperators and thereby avoid the potential costs of being cheated. Croft et al. (2006) quantified the social network of a wild guppy (*P. reticulata*) population and found stable, long-term associations between pairs of females that could persist for up to at least 1 month. When pairs of guppies from this population were observed within a predator inspection context, pairs of strongly associated females were more likely to act in a cooperative manner – e.g., more frequently exchanging lead positions during inspection – than weakly associated females. These results suggest that guppies may be able to preferentially associate with cooperative individuals and thereby reduce the potential costs of cooperation.

While joint predator inspection may represent a form of reciprocity, this interpretation has not been without criticism (Connor 1995, 2010; Clutton-Brock 2009). In particular, clear evidence is lacking that predator inspection behavior has been selected to provide benefits to a cooperator's partner(s) or that acting cooperatively in this context incurs net fitness costs to an individual at the

time it occurs (Clutton-Brock 2009). It has been suggested that joint predator inspection may be more parsimoniously viewed as a form of cooperation based on mutualism (Connor 1995).

Mutualism

Whereas reciprocity involves net fitness costs to an individual at the time that it offers assistance to another, cooperation based on mutualism generates inevitable shared benefits to all parties involved (Connor 1995; Clutton-Brock 2009). For example, cooperative foraging may increase the per capita success of each individual forager relative to that which they would experience when foraging alone. By garnering inevitable benefits from engaging in cooperative behavior, mutualism removes the temptation for individuals to cheat by withholding their cooperation. Cooperation based on mutualism may also be cognitively simpler to employ than reciprocity, as there is no need to remember the identities and past behavior of potential cheats. For this reason, mutualisms are predicted to be widespread in the animal kingdom (Clutton-Brock 2009).

Group foraging has been observed in numerous fish species and can range from fairly uncomplicated situations in which individuals travel together as a hunting group but do not coordinate with one another in terms of detection or capture of specific prey items (e.g., Arnegard and Carlson 2005) to more complex associations in which individuals coordinate to capture a particular prey item and can undertake different behavioral roles during a hunt (e.g., Bshary et al. 2006; Strübin et al. 2011).

The weakly electric African mormyrid fish, *Mormyrops anguilloides*, form nocturnal hunting groups and detect their cichlid prey via distortions in self-generated electric fields (Arnegard and Carlson 2005). Foraging success was greater in hunting groups as compared to lone foragers, though *M. anguilloides* within groups did not appear to coordinate their hunting efforts during capture attempts. It may be that improved foraging success within groups resulted from failed capture attempts by one hunter generating capture opportunities for other group members.

Collaborative hunting has been observed in the yellow saddle goatfish (*Parupeneus cyclostomus*), where stable foraging groups hunt for piscivorous prey within coral reefs (Strübin et al. 2011). During a hunt, prey fish are often chased into crevices and other shelters within the reef. When this occurs, members of the hunting group are more likely to adopt positioning that maximizes the group's ability to cut off potential escape routes (Fig. 3). This level of coordination suggests individual goatfish adopt different roles during a hunt – i.e., directly chasing prey versus blocking off potential escape routes – and the role that an individual adopts in any given hunt varies depending upon context.

Both of the examples described above represent likely cases of individuals generating coincidental benefits for their group mates as a result of their own self-serving behavior (Connor 1995). For example, when a group of yellow saddle goatfish are chasing a prey item, the individual that initiated the chase is likely to be nearest to the prey and therefore most likely to succeed at capturing the prey via direct pursuit. Other group members are unlikely to overtake the lead fish. However, by deviating from the path of pursuit to cut off potential avenues of escape, they may on average enhance their own

capture probability. Such coordination is likely to increase the average hunting success of a group, thereby generating shared benefits for each hunter.

While cooperative breeding groups often involve individuals providing assistance to non-descendant kin, in which cooperation can be maintained by indirect fitness benefits (see above), unrelated individuals may also provide help in some cooperatively breeding species (Wong and Balshine 2011; Kingma et al. 2014). The group augmentation hypothesis may help to explain cooperative breeding under some of these circumstances. Group augmentation occurs when subordinate nonbreeders help to raise their group's reproductive success and gain direct fitness benefits, such as an increased probability of survival, by being part of a larger group (Kingma et al. 2014). For group augmentation to function, it requires that: (1) helpers contribute to greater reproductive success for breeders, (2) at least some offspring remain within the group, and (3) living within a large group provides benefits to its members. When these group-living benefits result from the inevitable self-serving behavior of other group members, helping behavior can be selected for even in individuals unrelated to the breeders.

Cooperation Among Fishes, Fig. 3 Hunting groups of yellow saddle goatfish that had cornered prey within a coral refuge were more likely to adopt positioning that maximized spatial distance between individuals and minimized probability of prey escape. A prey refuge is represented by a circle divided into equal quadrants, with the location of the individual who initiated pursuit indicated. In hunting groups made up of two fish, maximal

interindividual distance would constitute adopting positions 180° opposite of one another. In groups of three fish, individuals should position themselves each within a separate quadrant. Shown are the frequencies expected if individuals positioned themselves at random (black lines) and the observed frequencies (bars) (Reprinted with permission from John Wiley & Sons, Inc. © 2011)

Helping in the cooperatively breeding cichlid, *N. pulcher*, does appear to meet the general criteria required for group augmentation to function. Helpers in *N. pulcher* contribute to greater reproductive success for breeder individuals, in that groups with more helpers successfully reared more young (Balshine et al. 2001; Brouwer et al. 2005). Further, there is some degree of philopatry in this species, meaning that offspring often remain with the group for some amount of time (Dierkes et al. 2005). This is important in that some of the effort put towards raising offspring results in increased group size in the future. Finally, larger group size in *N. pulcher* correlates with reduced predation risk and increased survival for both breeders and helpers (Balshine et al. 2001; Heg et al. 2004).

By engaging in helping behavior, helpers in *N. pulcher* can generate benefits for themselves. In the short-term, some acts of cooperation generate immediate benefits to the helper individual, such as by reducing predation risk through shelter excavation (Heg et al. 2004). Eventually, those young that survived as a result of the helper's assistance can benefit the helper through dilution effects – i.e., providing safety in numbers – as well as engaging in predator vigilance and assisting in territorial defense (Balshine et al. 2001; Heg et al. 2004). While there is a time lag between the assistance provided to help rear young and the eventual benefits generated by those young, there is no risk of exploitation as there is in reciprocity-based cooperation. Offspring that remain in the group will enhance the fitness of the helper simply by acting in self-serving ways.

Manipulation

Manipulation involves inducing other individuals to engage in cooperative behavior that either increases the manipulator's fitness or avoids outcomes that conflict with the manipulator's interests (Clutton-Brock 2009). An excellent example of such manipulative tactics can be found by examining the relationship between the cleaner wrasse (*Labroides dimidiatus*) and its clients.

Cleaner wrasse establish cleaning stations on coral reefs throughout the tropical Indo-Pacific and consume the ectoparasites of client fish who visit these stations (Trivers 1971). However, the wrasse actually prefers to consume its client's mucus instead of its ectoparasites, thereby establishing a conflict of interest (Grutter and Bshary 2003). A wrasse that consumes its client's mucus instead of its ectoparasites is cheating from the client's perspective in that the client loses valuable – and energetically costly to produce – mucus without gaining benefits in exchange. In particular, nonpredatory client fish are presented with a dilemma in that they have no means to exploit a cheating wrasse in return – e.g., eating the wrasse itself. This creates an asymmetric interaction where cleaners have the choice of either cooperating with or exploiting their nonpredatory clients, while the clients lack such a choice.

Despite the potential for cheating, most cleaner-client interactions are largely cooperative. Clients employ manipulative control mechanisms that are effective in promoting cooperation in cleaner wrasse. Clients who have been cheated can respond by punishing the wrasse through chasing (Bshary and Grutter 2002), terminating the current cleaning session, and/or switching to a different cleaner station for future sessions (Bshary and Schäffer 2002). Given that cleaner wrasses generally feed against their preferences – i.e., consume ectoparasites instead of client mucus – these control mechanisms appear effective at stabilizing cooperation between cleaners and clients. Essentially, client fish manipulate cleaner wrasse to behave in ways that differ from how cleaners would act if their behavior was unconstrained. Further work in this system has examined cooperation between multiple cleaners simultaneously inspecting the same client – where if one cleaner cheats its client, its partner cleaner also suffers the resulting costs but without gaining any benefits – to better understand the cooperative dynamics of this system (Gingins and Bshary 2015).

Alternating exchanges of egg parcels in some hermaphroditic fish species may represent a manipulative tactic to promote reciprocal fertilization of each individual's valuable eggs. The

black hamlet (*Hypoplectrus nigricans*) is a simultaneous hermaphrodite in that it possesses both eggs and sperm simultaneously (Fischer 1988). These fish spawn during the last 2 h of the day, during which pairs join up together. A pair alternates courtship displays prior to one individual releasing a parcel of eggs to be fertilized by its partner. As the spawning interaction continues, individuals alternate between fertilizing their partner's eggs and releasing their own parcels. Over the course of a single spawning period, each individual on average releases about five such parcels.

When viewed solely within the context of a dyadic interaction between just two individuals, cooperative courtship interactions between *H. nigricans* pairs may represent an example of TFT reciprocity (see above). Eggs are more energetically costly to produce than sperm. As a result, black hamlets could be tempted to cheat by fertilizing its partner's egg parcel with cheap-to-produce sperm without subsequently releasing a costly parcel of its own. Evidence suggests that if a black hamlet fails to release an egg parcel when it is their turn to do so, their partner may "retaliate" by waiting longer before releasing another parcel of eggs to be fertilized (Fischer 1988).

Some authors have argued that egg parcelling represents a manipulative strategy that promotes cooperative behavior between courting individuals (see Connor 2010 and references therein). If individual A released all of its eggs at once, that would leave it vulnerable to having individual B fertilize its eggs and then leave to seek additional mating opportunities without providing eggs for A to fertilize in turn. By parcelling their eggs, black hamlets are manipulating the costs and benefits of their partner's options. It is generally more beneficial for their mating partner to stay and exchange parcels than to leave after fertilization and pay the time and energy costs of finding a new mating partner.

Helping behavior of subordinates unrelated to the breeding individuals within cooperatively breeding groups of *N. pulcher* was discussed above in terms of shared mutualistic benefits. Pay-to-stay models propose another mechanism that may promote helping behavior by unrelated

subordinates. As described above, belonging to a group enhances survival in *N. pulcher* (Balshine et al. 2001; Heg et al. 2004). Pay-to-stay models propose that subordinates trade helping behavior for being allowed to remain on the group's territory (Wong and Balshine 2011; Fischer et al. 2014).

One of the assumptions behind pay-to-stay models is that subordinates are costly to dominant breeders through competition over resources and/or reproduction. If so, then a key prediction of pay-to-stay is that subordinates that do not provide help should be punished and/or evicted by breeder individuals. Such a pattern was observed at least in small groups of *N. pulcher*, where subordinates who were physically present – but experimentally prevented from helping – received increased aggression from breeders (Fischer et al. 2014). In this case, dominant breeders induce subordinates to engage in potentially costly helping behaviors through the threat of punishment and/or eviction from the territory.

Conclusion

Examples of cooperation in fish are found in a wide variety of species and contexts, including mating, foraging, anti-predator, and territorial behaviors. This entry has provided a broad overview of the evolutionary mechanisms that maintain cooperation in nonhumans, as well as relevant examples within each category. Owing to their immense diversity in species, morphology, and behavior – as well as the relative ease of observation and experimentation for many species – fish will continue to represent valuable model systems going forward for examining both the proximate and ultimate explanations for cooperative behavior in nonhuman animals.

Definition

An actor performs a behavior which benefits one or more recipients; the actor may incur a fitness cost (altruism), the actor's fitness may remain neutral (byproduct), or the actor may gain a fitness benefit from the behavior (mutualism).

Introduction

Despite being vulnerable to exploitation, cooperation has been observed throughout the animal kingdom (Dugatkin 1997). The opportunity for a selfish partner to defect in a cooperative interaction by returning less than he or she received, or by not contributing as much effort as other partners and freeriding, raises the questions of how cooperation evolved and how it is maintained.

Human society is defined by complex cooperation, which scales from simple interactions (for example, familiar individuals sharing resources) to complex interactions on a global scale (for example, unfamiliar individuals working together to build the International Space Station). Therefore, the study of cooperation in close phylogenetically related nonhuman primates (hereafter,

primates) offers us the opportunity to explore the selective pressures that shaped cooperative behaviors and the social factors affecting the maintenance of cooperation.

Evolutionary theory predicts that cooperation can occur when it increases one's inclusive fitness (i.e., sharing benefits with kin; Hamilton 1964) or when the short-term cost of offering benefits to others is balanced when those benefits are returned by the partner through reciprocation (Trivers 1971; Axelrod and Hamilton 1981). Kin selection and reciprocity are two mechanisms underlying the evolution of cooperation among primates (Kappeler and van Schaik 2006). Historically, kin selection and reciprocity have been discussed in how they relate to altruism, in which a behavior is costly to the actor and beneficial to the recipient in terms of fitness consequences. Here, these mechanisms are discussed in the broader context of cooperation, in which a behavior benefits the recipient without explicit cost to the actor – the actor may or may not benefit from the cooperative interaction. Kin selection is pervasive among cooperative primate interactions (Silk 2002) and helps to explain cooperative breeding in the Callitrichidae (a family of New World Monkeys including marmosets and tamarins). There is abundant evidence for reciprocally patterned behavior in wild primates, but evidence for contingent exchanges in a laboratory setting is weak (reviewed in Hall and Brosnan 2016).

Primates' aversion to inequity underpins their understanding of the features that make another individual a good cooperative partner. If a primate can judge his or her own outcome relative to others', he or she can choose partners that distribute rewards fairly (reviewed in Hall and Brosnan 2016). If a partner does not distribute rewards fairly, primates can exert partner control mechanisms such as punishment. Partner choice and punishment are mechanisms that contribute to the maintenance of cooperative interactions.

Complementary studies of primates in both wild and laboratory settings will strengthen our understanding of the functions and mechanisms of cooperation.

Ultimate Mechanisms of Cooperation

Kinship

Kinship plays a large role in shaping the relationships of members of the highly social order Primates, including dominance hierarchies, coalitions, and the organization of social networks. Additionally, kinship can shape life histories: the presence of a father, grandmother, aunt, or juvenile sibling to care for new infants can affect an individual's reproductive performance. In this section, the role of kinship in cooperative interactions is described, particularly the roles of kin selection and nepotism and of cooperative breeding.

Kin Selection and Nepotism

Kin selection, first described by Maynard Smith (1964), is a mechanism by which costly acts that benefit others (altruism in particular, and cooperation more generally) can occur, when the actor shares a degree of relatedness with the recipient. Any social interaction which incurs an investment of time, such as grooming, can be considered costly because that time could be invested in other activities such as foraging. As most primates are female philopatric, it is common for females to become nepotistic in their interactions with others. For example, in macaques (*Macaca fuscata*, *M. mulatta*, *M. nemestrina*, *M. radiata*), baboons (*Papio cynocephalus ursinus*), and vervets (*Cercopithecus aethiops*), females tend to invest more time in grooming, resting with, and providing infant care to members of their matriline than to nonkin (reviewed in Silk 2002; Cheney & Seyfarth 1984). They also spend more time, and are more tolerant of, feeding with kin (*ibid.*). Additionally, these females are more likely to provide coalitionary support to kin (*ibid.*). These interactions directly benefit the recipient and also indirectly benefit the actor, because the two share a degree of relatedness due to common ancestry. Additionally, these cooperative interactions may also benefit the actor through symmetry-based reciprocity (described below).

Cooperative Breeding and Alloparenting

For primates of both sexes, but in particular for females, remaining in the natal group with generations of matrilineal kin confers reproductive benefits, even when considering the risks of inbreeding. In addition to increased vigilance for predators, and other fitness benefits of interacting frequently with kin (per kin selection theory, above), the enhanced social support of an aunt or younger sibling to help care for a newborn has a positive impact on the survival rate of both mother and offspring (Hrdy 2007). Alloparenting, or the providing of care to infants by individuals other than the infant's mother, comprises several behaviors: carrying or transporting infants, provisioning food and sometimes nursing, babysitting, support in agonistic interactions, and protection against infanticide. Genetically related nonbreeders increase their inclusive fitness by helping, and additionally, mothers allowing nulliparous daughters the opportunity to practice caring for younger siblings gives them the experience they need to be better mothers when the time comes (Hrdy 1999).

For obligate cooperative breeders in the family Callitrichidae (tamarins and marmosets), males carry the offspring – usually twins – up to 60 % of the time (e.g., common marmosets *Callithrix jacchus*), representing a significant energetic cost for the father, especially as the infants grow (Hrdy 2007). Male cotton-top tamarins (*Saguinus oedipus*) can lose up to 10 % of their body weight from carrying infants during the first 3 months after birth, though this is attenuated if additional helpers are available (Achenbach and Snowdon 2002). These parenting strategies allow for increased infant and mother survival as well as shorter inter-birth intervals.

Reciprocity

Cooperation among nonkin can evolve when partners take turns exchanging goods or services; this was formally defined as reciprocal altruism by Trivers (1971), but this is somewhat of a misnomer. As the actor ultimately benefits from the returned favor, there is a direct fitness advantage to cooperating, whereas to be defined as altruistic, the actor must incur a cost. In this section, the role

of reciprocity in cooperative interactions is described, in particular the types of reciprocity, and a discussion of biological markets theory.

Brosnan and de Waal (2002) proposed three levels of reciprocity. First, symmetry-based reciprocity suggests that reciprocity within a relationship exists simply because of the symmetrical nature of the relationship itself. For example, because A and B spend more time together, their actions will naturally benefit each other, without contingency between actions. Second, attitudinal reciprocity suggests that there is a contingent relationship between A's kind act towards B that elicits a feeling of good will in B towards A, thus increasing the likelihood that B will return a favor to A. Third, calculated reciprocity suggests that A and B cognitively keep track, in a tit-for-tat manner, the exchanged favors between them. However, it is difficult to distinguish between symmetry-based and calculated reciprocity from correlational data; data should be analyzed sequentially to determine whether an act by A towards B increases the probability of B acting towards A.

Grooming

In a meta-analysis of long-term grooming data from 22 primate species from both Haplorhini and Strepsirrhini, Schino and Aureli (2008) found that female primates preferentially groom the individuals that groom them the most, even when controlling for maternal kinship. Within a grooming session, there is a positive correlation between the durations of time that closely ranked chacma baboon (*P. c. ursinus*), bonnet macaque (*M. radiata*), and capuchin (*Cebus capucinus*) partners invest in grooming each other (Barrett et al. 1999; Manson et al. 2004).

Food Sharing

Feistner and McGrew (1989) define food sharing as when food-motivated individuals voluntarily transfer defensible food items to others, and they review examples of food sharing in wild primates. One hypothesis to explain food sharing among primates suggests that sharing only occurs reactively to relieve pressure from harassing conspecifics, whereas a second suggests that reciprocity

underlies a service economy in which food is one of many goods or services to exchange (see section on “[Biological Markets](#)”, below). Gilby (2006) found strong support for the harassment hypothesis in chimpanzees (*Pan troglodytes schweinfurthii*) but only mixed support for the reciprocity hypothesis: food possessors were more likely to share with frequent grooming partners but due in part to an effort to reduce their harassment. To compare the rates of reciprocal exchange of food between partners, Jaeggi et al. (2010) determined that food exchanges were reciprocal among tolerant chimpanzees but mainly unidirectional among despotic bonobos (*P. paniscus*). De Waal (1989) found a positive correlation between the rates of transfer of food in either direction between chimpanzee dyads, supporting the reciprocity hypothesis.

Evidence of the contingent reciprocal exchange of food between primates in a controlled laboratory setting, however, is weak. De Waal (2000) describes that capuchins (*C. apella*) passively transferred food through a mesh barrier in a reciprocal, but not contingent, manner. Even in low-cost situations, for example by choosing to pull a tray with food rewards for both partners versus pulling a tray with a reward only for the actor, chimpanzee and cotton-top tamarin subjects' behavior is not contingent on their partner's prior choice (Brosnan et al. 2009; Cronin et al. 2009).

Coalitions

Coalitionary support in agonistic interactions is another behavior thought to be costly to the actor and beneficial to the recipient. Among chimpanzees, rhesus and stump-tailed macaques (*M. arctoides*), there was significant reciprocity for beneficial interventions, but only chimpanzees significantly intervened in harmful ways, demonstrating a rudimentary system of revenge (de Waal and Luttrell 1988).

Biological Markets

Reciprocated exchanges need not be paid back in the same currency: often goods and services are traded in a biological “marketplace,” including grooming, food sharing, coalitionary

support, and mating access (Noë and Hammerstein 1994). There is continued debate as to whether primates must cognitively keep track of the value of multiple commodities over extended time or whether they behave based on current needs and the availability of the desired goods/services.

Hemelrijk (1994) confirmed that female long-tailed macaques (*M. fascicularis*) offer more support to other females who had recently groomed them than to those who had not, and that this outcome was directional: A supported B more after B had groomed A, but not after A had groomed B or if no grooming interaction had occurred prior to the agonistic interaction with C. In a meta-analysis of 14 species from both Haplorhini and Strepsirrhini, Schino (2007) showed that, in general, female primates direct their grooming efforts at higher-ranking individuals in exchange for their support in agonistic interactions.

Grooming can also be traded for food and vice versa: in naturalistic studies of chimpanzees and bonobos, it was found that both species showed short-term contingencies between the two commodities, but that controlling for long-term relationship characteristics diminished the effect for chimpanzees (Jaeggi et al. 2013). This result highlights the issues surrounding the timeframe of measurement; as evidence for short-term reciprocity is lacking, it is difficult to determine the span of time necessary for exchanges to become balanced.

Proximate Mechanisms for Maintaining Cooperation

Inequity Aversion

Brosnan (2006) proposed that aversion to inequity underlies the evolution of cooperative behavior. Primates' responses to inequity vary based on multiple factors: the presence of a task elicits a stronger response, dominance and certain personality traits predict a more adverse reaction to inequity, and responses are attenuated by the duration and quality of the partners' relationship (reviewed in Hall and Brosnan 2016). The inequity response

did not evolve through homology in the primates and is not an artifact of large brain size or living in a large social group, rather, it occurs in species that regularly cooperate with nonkin, including chimpanzees, bonobos, capuchins, rhesus, and long-tailed macaques but not in those that do not, such as orangutans (*Pongo spp.*), squirrel monkeys (*Saimiri boliviensis*), or cooperatively breeding tamarins, marmosets, and owl monkeys (*Aotus spp.*) (*ibid.*). Responding to inequitable outcomes allows primates to choose cooperative partners based on a more fair reward distribution (*ibid.*).

Partner Choice

In order to maintain cooperation in social groups and defend against defectors, primates exhibit partner choice. In cooperative interactions, primates pay attention to the characteristics of their partners, in addition to the relative reward outcomes. Due to the lack of partner choice in most laboratory studies (e.g., due to limited subject availability or lack of tolerance between partners), Molesti and Majolo (2016) introduced a cooperation apparatus – a string pulling task – into a group of wild Barbary macaques (*M. sylvanus*) to determine the factors affecting partner choice in an open-choice group scenario. They found that macaques had more success at the task when they chose partners with whom they were tolerant and shared a strong social bond (kin or not) and also found effects of similar rank, age, sex, and temperament.

Punishment

Another mechanism to deter defection and freeloading in cooperative interactions is punishment – whether by the abandoned partner or by a third party. Punishment, or the threat of it, can prevent individuals from defecting in future interactions. There is, however, limited evidence of punishment in primates, possibly due to the higher cost associated with punishment than with choosing a new partner from an available pool of multiple partners. Chimpanzees, for example, will punish those that steal food from them but will not punish based on unfair outcomes alone (Jensen et al. 2007).

Conclusion

Studying the underlying mechanisms of cooperation in primates can help us better understand the evolutionary path and function of the behavior, without the confound of human culture. When individuals interact with genetically related group members, cooperation is likely explained by the mechanism of kin selection: though the actor may incur a cost, ultimately he or she benefits from improved inclusive fitness. When unrelated individuals cooperate, reciprocity may be the underlying mechanism, whether symmetry-based, attitudinal, or calculated. It is not uncommon for these two mechanisms to share some overlap. By learning more about the selective pressures that may have molded a behavior, we can better tease apart the proximate motivations to cooperate from the ultimate functions of doing so. Understanding how these traits evolved, and how the mechanisms of partner choice and punishment help to maintain cooperation, can give us insight into the importance of cooperation for preserving social relationships.

Though there is good evidence of cooperation in primates, questions remain with respect to the influence of time on the balancing of given and received favors and the influence of cognition for tallying them. Short-term contingent reciprocity is difficult to show in a laboratory setting, and difficult to test with unfamiliar individuals, yet these concerns could be an artifact of the experimental setup, for example, lack of partner choice. Due to the difficulty in distinguishing symmetry-based and calculated reciprocity, the question of cognition remains sidelined.

Definition

Cognitive processes and mechanisms underlying human ability to cooperate with others

Introduction

Living in groups implies the ability to cooperate and coordinate individuals' behaviors. In human societies, cooperation goes far beyond relations based on kinship, extending both in space and time. The human ability to cooperate with others, especially unrelated others, is a challenge for the evolution theory as it seemingly contradicts the notion of "self-interest" as the key driver of behavior. Cooperation implies behavior, which benefits others, often without immediate returns for an individual. Although evolution theory considers cooperation with little or no cognition at all, in human societies it depends on advanced cognitive abilities. To establish and maintain complex cooperation, individuals must be able to recognize others' identities as well as their states and intentions, monitor their actual behavior, keep memory for past interactions, calculate potential costs and benefits for long-term interaction, control one's behavior to receive a delayed reward, recognize deception, and others. Performing such tasks requires both general cognitive abilities and more specialized skills of social cognition, which is a crucial prerequisite for cooperation in humans.

Social Cognition

Social cognition is a set of abilities needed for social tasks, i.e., tasks which involve other

individuals and interaction with them. Although any cognitive process or ability can be related to social tasks, it is useful to recognize those ones which constitute the distinctive features of social cognition and its key functions. In a recent review, F. Happé, J. Cook, and G. Bird identified eight key components of social cognition all of which are important for cooperation (Happé et al. 2017, p. 247):

1. Social affiliation and motivation. The essential part of human cooperation is group-based cooperation, i.e., individuals prefer to cooperate with the members of their own group (ingroup). Such a tendency is a result of social motivation and the need of belonging. In terms of social cognition, social affiliation is based on processes of social categorization and social identity. Social categorization means that both oneself and others are perceived as members of social groups and categories rather than individuals, whereas social identity implies that individuals' group membership constitutes a part of self-identification. Identifying others in terms of group membership determines the readiness for others-oriented actions, expectations of others' group-directed behavior, and the decisions to cooperate.
2. Agent recognition, i.e., identification of social agents and their identity. As cooperation typically implies actual or potential repetitive interaction, agents must know with whom they have a deal and mutual obligations. In case of indirect reciprocity or unconditional cooperation, agents also must be sure their efforts are directed toward an appropriate other.
3. Biological motion perception, action recognition, and imitation. As cooperation manifests itself via observable action, agents must be able to identify and recognize what others actually do. Imitating others' actions, in turn, is an important part of social behavior, necessary for learning, collective cohesion, and understanding others' actions.
4. Emotion recognition. As behavior strongly depends on agents' affective states, they must

be timely and correctly recognized to maintain smooth interaction, predict others' behaviors, and determine their readiness for cooperation and reciprocity.

5. Empathy. The ability to experience the same affective states as that of others is not only a way to understand them and their intentions, but it also stimulates the readiness for other-benefiting behavior.
6. Social attention. Living in group means that individuals must constantly monitor the social environment and selectively focus on important social stimuli. Social attention is largely automatic and supports fast detection of social stimuli and recognition of their key social feature such as group membership or status.
7. Social learning. Learning from other individuals, either direct or by imitation, can also be related to cooperation, not only because it transfers skills and experience of cooperative behaviors but also because learning as a kind of social interaction is itself a form of cooperation.
8. Theory of mind (ToM). ToM, i.e., the ability to infer other's intentions and states of mind is probably the most important type of social cognitive processes as it helps to predict others' behavior and make strategic decisions. ToM implies the ability to take third person perspective and look at the situation by others' eyes. Understanding others' evaluation of the situation, possible benefits and losses of cooperation, as well as their preferences and attitudes helps to detect potential deception and decide whether it is worth cooperating with them or not.

The listed types of cognitive processes are not necessarily separate from each other. The ongoing discussions consider various scenarios of how they can be related to each other including partial overlapping, developmental relations, or even considering some of them as parts of the same process (Happé et al. 2017). However, the very idea of social cognition implies that humans as well as other social species have cognitive

abilities evolutionary developed and tuned to support social bonding and cooperation.

Two Types of Cooperation

There are two types of cooperation generally recognized by the evolution theory. The first one is largely unconditional and takes place among related individuals, e.g., kinship. Cooperation in this case depends on established relations with others and is generally explained by reference to kin or group selection. As this type of other-benefiting behavior depends on specific social markers of a partner, it can be termed group-based cooperation. This means that the decision to benefit other individuals is determined by their social affiliation with an agent, i.e., group membership. The second type of cooperation occurs between unrelated individuals and implies more strategic behavior. Decisions to cooperate in these cases are generally conditional, i.e., they depend on expectations of mutuality and returns, either direct or indirect. The decision to cooperate, unlike the first type, is a choice rather than imperative.

In regard to social cognition, these types of cooperation have important differences, which can be partially related to the dual-process cognitive theories. According to them, two types of cognitive processes exist in human mind and compete during decision-making (Kahneman and Frederick 2002). The first one is automatic, fast, and very efficient but less sensitive to contextual information. The second one is slower, more deliberate, rational, time-consuming, and sensitive to context. The dual-process approach was applied to the study of social cognition and cooperation, suggesting that intuitive (social heuristics) and deliberate decision-making are the two possible ways for making decisions in social dilemmas and providing different solutions (Rand 2016). Unconditional, group-based cooperation generally relies more on automatic processes, whereas strategic behavior is more associated with deliberate cognition. At the same

time, the distinction between the two types of cooperation as well as the idea of pure automation and deliberation are an idealization. In reality, the two types of cognition may act in parallel and interact with each other and are involved in each type of cooperation, so that, for example, automatic decisions (social heuristics) can favor cooperation with unrelated others and in the absence of reciprocity, due to their cost-efficiency (Bear et al. 2017). Despite this, various types of cooperation require different social cognitive skills and processes briefly described below.

Social Cognition in Group-Based Cooperation

The group-based cooperation is typically associated with kin selection mechanisms and needs only the minimal cognitive abilities or none of them at all, as it takes place, for example, among the social insects (Brosnan et al. 2010, p. 2699). The key feature of such helping behavior is that it is largely unconditional, i.e., doesn't depend on others' behavior. However, identification of co-species and the members of relevant social entity (e.g., a hive) is a necessary prerequisite for such cooperation. In species such as microorganisms or insects, identification of cooperators is typically based on chemical signals. In the most developed species, identification of appropriate recipients of helping behavior is more advanced and involves variety of psychological and cognitive mechanisms of self-categorization and social identity construction.

Human social identity is multiple and complex. Lay people identify their own and others' membership in various types of groups such as intimacy groups, social categories, task groups, and loose associations (Lickel et al. 2001). These types of groups differ in their personal significance, perceived homogeneity, and other characteristics, important for cooperative behavior. Individuals constitute their social identity from numerous group memberships of various types. Their own and others' perceived group membership is dynamic and constantly updating, different social categories become more or less salient in various contexts and overlap with each

other (Crisp and Hewstone 2006; Kang and Bodenhausen 2015). Some group memberships are considered to be especially stable and of highest priority. These include gender, age, race/ethnicity, and language (Kinzler et al. 2010). Recognition of these group memberships is fast and automatic although more controlled processes can also be involved in their representation. They are recognized by children and even infants, thus confirming that the human mind is evolutionary tuned to effectively manage the complexity of the social world.
